Treatment.—When there are vasomotor symptoms oestrogens should be given in the smallest dose that proves effective. The synthetic oestrogen, ethinylestradiol, can be given in an initial dose of 0.01 mg. twice daily or 3000 units or more of the natural oestrogen, oestrone, can be given daily. It is recognised that some patients may require much higher dosage and then nausea may result, especially with synthetic preparations. Although oestrogens are carcinogenic in laboratory animals this should not prevent their administration in the climacteric when they are indicated. A more realistic disadvantage is the possibility of uterine bleeding during the time of administration or on withdrawal. For this reason minimal doses are advised and when the oestrogen is to be discontinued withdrawal should be gradual. Should uterine bleeding take place in a post-menopausal patient, receiving oestrogens or not, uterine carcinoma should be excluded. Sedatives and simple psychotherapy are often beneficial and adiposity and hirsutism are dealt with on the lines advocated in previous sections.

SEXUAL PRECOCITY

Synonyms.—*Pubertas Præcox*; *Macrogenitosomia*.

Definition.—The attainment of sexual maturity in childhood some years before the normal time of puberty. True sexual precocity is due to pituitary or hypothalamic-pituitary gonadotrophic stimulation. Pseudo-sexual precocity is due to hyperactivity of the adrenal cortex, or of a gonadal tumour, in childhood, leading to premature but incomplete sexual maturity.

Ætiology and Pathology.—Sexual precocity may be due to a variety of causes, which ultimately belong to one of three groups, primary gonadal; primary adrenal; primary pituitary or hypothalamic-pituitary. Thus the underlying lesion may be an adenocarcinoma of the testis, a granulosa cell tumour of the ovary, an adenoma or adenocarcinoma of the adrenal cortex, a pineal tumour (which acts pathologically by mechanically stimulating the hypothalamic pituitary mechanism and not by producing any specific hormone of its own), encephalitis, internal hydrocephalus or a third ventricle tumour. There is also an idiopathic familial type of sexual precocity. Whatever the mechanism, the result is a hypersecretion of androgenic or oestrogenic hormone.

Symptoms.—In boys, the sexual precocity is shown by enlargement of the penis, development of hair on the pubis and to some extent on the face, and often considerable strength, the Hercules type. In true sexual precocity the testicles are enlarged in proportion to the penis, whereas in pseudo-sexual precocity the testicles, except when there is a testicular tumour, are small and atrophic. This is due to the fact that adrenal androgens inhibit pituitary gonadotrophins. The boys will show obvious sexual behaviour, even running after and attacking adult women, masturbating against their legs, which they may clasp with great strength and may bite with anger if frustrated. Seminal emission is rare with pseudo-sexual precocity. The precocity may begin in very early childhood.

With girls, there are clinically two main types. When the condition is due to ovarian hyperactivity, either primary or secondary to a hypothalamic-pituitary stimulus, it is manifested by qualitatively normal sexual development, pubic hair, well-formed breasts, menstruation and even pregnancy, the last having been recorded as early as 6 years of age. With adrenal tumours, menstruation is usually absent, the clitoris enlarged, the voice deep, and hirsutism occurs on the face and body, as in virilism. These manifestations are due to the secretion of androgenic hormone by an adrenal tumour but adrenal oestrogens may also be secreted.

NEUROBLASTOMA OR SYMPATHOBLASTOMA

This highly malignant tumour is found usually in young children but it can arise at any age, and on rare occasions, when it is congenital, it can be large enough to obstruct labour. Symptoms and signs are more often due to metastases than to the primary growth. In the Pepper type, which affects children under 1 year, the liver is enormously enlarged and the disease is rapidly progressive. In the Hutchison type, which is more common in older children, metastases are found in bones and the progress of the disease is more gradual. The skull is invaded, especially in the region of the orbits, and bruising of the eyelids followed by exophthalmos are amongst the commonest presenting symptoms. Skull radiograms are indistinguishable from those in sarcoma, showing fine spicules of bone radiating from the outer table. Secondary tumours of the long bones are usually palpable and radiograms are here diagnostic. The periosteum is raised by subperiosteal growth which does not involve the cortex until the later stages of the disease.

Prognosis—Death is usual within a year, but examples of spontaneous recovery are on record.

Treatment—Excision of the primary growth can be combined with radiotherapy, but the results are unsatisfactory.

GANGLIONEUROMA

This is a rare benign tumour which produces symptoms only because of its size. It is found in childhood and in adult life.

THE SEX GLANDS

Hypogonadism may be secondary to failure of pituitary function, as has been described in previous articles, *e.g.* Simmonds's disease and Fröhlich's syndrome, or it may be a primary failure of gonadal function, *e.g.* eunuchoidism, climacteric. The latter condition in males is not generally recognised, but is met with in some men over 50, with loss of libido and potency, hot flushes, anxiety and inability to concentrate, the symptoms are ameliorated by testosterone therapy. Impotence in man is not infrequently met with at all ages, and is usually psychogenic. Whereas organic impotence, *e.g.* after traumatic castration, responds dramatically to testosterone, psychogenic impotence does not. The latter may be ameliorated but rarely cured by psychotherapy. Temporary functional impotence is more common than is generally realised, and is caused by excessive anxiety or fatigue.

EUNUCHOIDISM

Definition.—A condition of primary hypogonadism, or agonadism, originating in embryo, or before puberty. The term is usually restricted to males and this will be observed in the description of this section, but female eunuchoidism does occur. The term eunuchism is sometimes applied to complete absence of gonadal function.

Ætiology.—The condition is often genetically determined, and there is no obvious cause for the failure of gonadal development, or it may result from bilateral testicular atrophy following mumps, or, rarely, operation for bilateral inguinal hernia. Very rarely, also, both gonads may be involved in strangulated hernia, and be removed. In certain religious sects, castration is performed before puberty in all males, and this

operation was at one time carried out to provide eunuchs (meaning "guardian of the couch") in harems.

Symptoms.—The epiphyses of the long bones remain open until the third or fourth decade, or longer, and as there is no deficiency of growth hormone, all true eunuchs tend to be tall, often very tall. The length of the limbs is much greater than the measurement from the head to the pubis; in normals such measurements are approximately equal. The testes are absent, atrophic or infantile, and the penis small and flaccid. Libido and potency are absent. The secondary sexual characteristics are absent and the patient has a smooth hairless face and high-pitched voice. The pelvis may be of neutral type, or unusually broad for a man. Pubic hair may be present, but it is scanty and limited horizontally. There is a thin type and a fat type, which fact complicates our conception of the disease, but this appears to depend on an inherent endocrine constitution. Thus, whereas in cattle, sheep and oxen, castration is undertaken to produce fatness and invariably does so, in dogs early castration produces fatness in only some 50 per cent. Even the thin eunuchs tend to put on weight after the age of 40.

Complications and related Syndromes.—A syndrome consisting of gynæcomastia, very small testes, azoospermia and increased amounts of gonadotrophins has been described by Klinefelter, Reifenstein and Albright, biopsy of the testes showing hyalinisation of varying degree in the spermatid tubules. The interstitial cells of Leydig appear numerous and prominent, but staining methods show that they are abnormal. The urinary 17-ketosteroids are usually decreased and most of the patients show some degree of eunuchoidism. Heller and Nelson described a similar group, but in which gynæcomastia was a less common finding. These contributions led to the theory that the seminiferous tubules secrete a substance called "inhibin", which inhibits the secretion of anterior pituitary gonadotrophins. Inhibin is said to be a hypothetical oestrogen-like secretion of the seminiferous epithelium. These conditions should be regarded as varieties of eunuchoidism in which some pathological process affects both the seminiferous tubules and the interstitial cells, although the near normal appearance of the latter may be deceptive. The clinical picture is fairly obvious and can be confirmed by the demonstration of an excess of pituitary gonadotrophins in the urine and by failure of the testes to respond to gonadotrophic injections. Biopsy of the testes is important for a complete evaluation, in particular in those rare cases where the size of the testes is not appreciably decreased. True eunuchoidism occurs only when the genetic or pathological processes are evident before or at puberty, but an incomplete post-puberty type is recognised. Primary anterior pituitary insufficiency may be associated with a eunuchoid-like condition, but the author does not think the term "pituitary eunuchoidism" should be permitted as it is confusing and conflicting with definition. It is obvious that in such a condition there is an absence rather than an excess of pituitary gonadotrophins in the urine.

Testosterone can be given by injection, 50 mg. of testosterone propionate in oil, twice or thrice weekly; or more conveniently by using the long-acting testosterone phenyl-propionate, injected once weekly or every 2 weeks in the same dosage. By subcutaneous implantation, 8 tablets of 100 mg. each, the effect will last for some 8 months. Methyl testosterone, 10 to 25 mg. tablets by mouth or under the tongue, three times a day are also effective. Sublingual absorption ensures the maximum potency, but swallowing the tablet is quite practicable and efficient, although only two-thirds as effective.

IMPOTENCE AND INFERTILITY

Apart from the association of impotency with obvious major endocrine disorders, organic endocrine impotency can be due to deficiency or absence of testicular androgenic secretion. Defined as such, it is a rarity, and it can be ruled out when secondary

In both sexes, sexual maturity is associated with premature dentition, and early union of the epiphyses. The latter results in ultimate dwarfism although initial growth is well above average. Although the instincts may be adult, the intellectual activity usually corresponds to the chronological age.

Diagnosis.—In girls, an enlarged clitoris and hirsutism suggest an adrenal tumour, whereas homosexual precocity, without hirsutism, may be due to an ovarian granulosa cell tumour, or, more commonly, bilateral adult development of the ovaries, or multiple cystic ovaries. Although, in the two latter instances, the initial stimulus is probably a pituitary one, there is often no gross detectable pituitary or hypothalamic pituitary lesion. In boys with an adrenal tumour, the testes remain infantile, although the penis is big, whereas with a primary pituitary, or hypothalamic-pituitary lesion, the testes tend to be developed to adult size and function. Pineal tumours may be manifested by ocular palsies, papilloedema, somnolence and other hypothalamic features such as polyphagia, adiposity, diabetes insipidus and disturbances in temperature. Precocious puberty may also occur with third ventricle tumours, aqueductal block following encephalitis lethargica, tuberculous or syphilitic meningo-encephalomyelitis, post-measles encephalomyelitis, supra-sellar tumours, neoplasms involving the floor of the third ventricle and tumours of the mamillary bodies and tuber cinereum. Ventriculograms and exploratory cranial operations may be necessary.

Prognosis.—Idiopathic or familial sexual precocity may proceed to a normal adult state. Adrenal and testicular tumours are usually malignant, whereas ovarian tumours are generally not so. Intracranial lesions may be fatal. Removal of adrenal or gonadal tumours tends to produce a reversion to normal in the absence of metastases.

Treatment.—Adrenal, testicular or intracranial neoplasms should, if possible, be excised. Oestrogens may control sexual behaviour in males with idiopathic or hypothalamic-pituitary precocity.

S. LEONARD SIMPSON

SECTION VIII

DISEASES OF THE DIGESTIVE SYSTEM

DISEASES OF THE MOUTH

STOMATITIS

CATARRHAL STOMATITIS

Ætiology.—Catarrhal stomatitis is common in ill-nourished children during dentition and in association with gastro intestinal disturbances. In adults it may result from excessive consumption of alcohol or highly seasoned food or excessive smoking. It is sometimes present in the specific fevers, and may also be caused by septic teeth and a dirty or badly fitting plate. It develops rapidly in very ill people whose mouths are not kept clean, especially if they sleep with the mouth open.

Symptoms.—The gums and lips may alone be affected. In other cases the whole mouth, including the tongue, is involved. The mucous membrane is red and dry, but excess of mucus may be secreted by the small buccal glands. The tongue is swollen and furred.

The mouth is uncomfortable, and occasionally actual pain is present, especially on mastication. The patient complains of a nasty taste, especially on waking, and fetor oris may be present. The general health is unaffected.

Treatment.—The teeth should be cleaned with special care, and the tongue kept as free as possible from fur by scraping. A mouth wash should be used after each meal, and glycerin of borax should then be applied to the inflamed parts.

ULCERATIVE STOMATITIS

Ætiology.—Ulcerative stomatitis is not a specific disease, but is, like catarrhal stomatitis, produced by the action of various irritants. It can develop from neglected cases of catarrhal stomatitis, and is a prominent symptom of mercurial poisoning and scurvy. The following are special varieties of the condition.

(a) RECURRENT ULCERATION IN ADULTS

Single or multiple superficial ulcers may occur on the mucous membrane of the cheeks, lips, tongue and gums. They have a grey surface with a red, but not raised, border, and the intervening mucous membrane is generally healthy. In severe cases, however, the ulcer is deeper and its base bright red. Each ulcer generally lasts only a few days, but a patient may have one or more in his mouth for months, or even years, without an interval. They are often very painful, especially on chewing, and they may make it impossible to take any acid food. Their ætiology is most obscure, the condition is aggravated by oral sepsis and ill-fitting plates, and some ulcers may begin as abrasions produced by the careless use of a tooth brush, but it appears to depend primarily upon some obscure constitutional defect. It is not associated with any disturbance in digestion or with any special form of gastric secretion. The saliva is not acid and the ulcers do not appear to be infective in origin. In some cases there is an undoubted nervous element in causation, and immediate cure may follow relief from anxiety, suspense or emotional strain.

No treatment beyond scrupulous attention to oral hygiene and the application

of silver nitrate to each ulcer as it appears is, as a rule, of any use. Cures have been reported from the use of nicotinamide, 100 mg., three times a day for a month.

(b) APHTHOUS (OR VESICULAR) STOMATITIS.

Ætiology.—Aphthous stomatitis occurs especially in children, either alone or associated with some febrile or digestive disorder. It is due to a filterable virus which is latent until activated by such an infection as pneumonia.

Symptoms.—The aphthæ consist of small slightly raised vesicles, each surrounded by a red areola. Within 24 hours the vesicles rupture, leaving grey ulcers, 2 to 4 mm. in diameter, with bright-red margins. The ulcers heal rapidly. They occur especially on the inner surface of the lips, the edges of the tongue and the inside of the cheek. In severe cases the pillars of the fauces may be affected. The mouth feels sore, and the child is unwilling to take food. Salivation is frequently present.

Treatment.—The mouth must be carefully washed after meals with potassium chlorate solution (gr. 10 to 1 fl. oz.). In severe cases the ulcers may be treated with silver nitrate.

(c) FOLLICULAR STOMATITIS.

Ætiology.—Follicular stomatitis may occur at any age, but especially in nursing women.

Symptoms.—The mucous follicles of the lips and cheeks become inflamed and swollen; the epithelium over them breaks down, and ulcers, 3 to 5 mm. in diameter, result. They may cause no symptoms, but more commonly they give rise to a considerable amount of pain on taking food and to reflex salivation.

Treatment.—The ulcers heal rapidly after being touched with silver nitrate

(d) MERCURIAL STOMATITIS.

See pp. 233 and 381.

(e) ULCERO-MEMBRANOUS STOMATITIS (VINCENT'S STOMATITIS).

Ætiology and Pathology.—Severe ulcero-membranous stomatitis is a contagious disease, caused by infection with the same spirochaetes and fusiform bacilli which cause Vincent's angina (see p. 537).

Symptoms.—All parts of the mouth and pharynx may be involved, but the margins of the gums are specially liable to be affected. The stomatitis is similar to that caused by mercury, and the gums may be so swollen and bleed so readily that scurvy is simulated. The breath has a characteristic fetid odour, and the tender gums may make mastication painful.

The disease is sometimes acute, but more often runs a chronic course and is often followed by pyorrhœa alveolaris. It generally gives rise to but little constitutional disturbance.

Treatment.—The teeth should be scaled, and the ulcerated margins of the gums treated by the application of 10 per cent. chromic acid for 1 minute, followed by hydrogen peroxide kept in the mouth for 2 minutes. Penicillin lozenges should be used by tucking one as high as possible into the buccal sulcus above the last upper molar. It will last from 1 to 3 hours and then should be replaced by another. One will last all night. This should be kept up continuously for about 4 days or until a day or two after acute symptoms have subsided. In severe cases intramuscular doses of penicillin should be given, 500,000 units daily for 4 days. The patient should be given 300 mg. vitamin C daily for a fortnight, followed by 50 mg. daily for 6 months. Sodium perborate should be used as a tooth-powder and hydrogen peroxide as a mouth-wash. Smoking should be forbidden.

(f) GANGRENOUS STOMATITIS.

Synonyms.—Cancrum Oris; Noma.

Ætiology.—This rare disease occurs in children, especially girls between the ages of 2 and 5, who live under very insanitary conditions. It generally develops during convalescence from an acute fever, especially measles, and less frequently scarlet and typhoid fever. It also forms part of the clinical picture of agranulocytosis (p. 756).

Symptoms.—A sloughing ulcer develops in the inside of the cheek or on the gums; it rapidly spreads and leads to brawny induration of the skin of the cheek. Occasionally it heals spontaneously, but more frequently it perforates the cheek or spreads to the tongue, chin, jawbone or eyelid and eye.

Cancrum oris is accompanied by severe constitutional symptoms, the patient being prostrated with a high temperature and rapid pulse. Diarrhœa or broncho-pneumonia frequently follows, and death generally occurs between 7 and 10 days from the onset.

Treatment.—The only adequate treatment for cancrum oris in children is to destroy the diseased part as completely as possible with the cautery. Intramuscular injections of penicillin should be given in massive doses related to the child's weight. For the treatment of agranulocytosis see p. 757.

THRUSH

Ætiology.—Thrush is most common in weak, emaciated infants with gastrointestinal symptoms, who have been fed with an unsuitable diet, and whose mouths have not been kept clean. Acid fermentation of food remnants leads to catarrhal stomatitis, and this is likely to be followed by thrush. Thrush occurs in epidemic form in badly managed institutions, being spread by dirty feeding-bottles. The disease may also occur in enfeebled adults in the late stages of tuberculosis, cancer and diabetes, and in severe febrile infections.

Pathology.—Thrush is caused by infection with *Candida albicans*—a fungus, the filaments of which form a dense felt-work in the superficial epithelial layer of the mucous membrane.

Symptoms.—Thrush generally appears first on the tongue, and then on the cheeks, lips, hard palate, tonsils and pharynx. In rare cases the entire buccal mucous membrane is covered, and the infection may even spread to the vocal cords, œsophagus and stomach. It begins as slightly raised, pearl-white spots, which gradually grow and then coalesce. The white material can be readily detached, leaving either intact mucous membrane, or, in more severe cases, a bleeding and ulcerated surface.

Diagnosis.—Adherent milk curds may superficially simulate thrush. In aphthous stomatitis the white patches are at first vesicles and then definite ulcers, and salivation is present in contrast to the dry mouth in thrush. A definite diagnosis can be made only with the aid of the microscope.

Treatment.—Thrush should be prevented by keeping the mouth clean and babies' bottles sterilised. It is important to improve the patient's general health as well as to give local treatment. The mouth should be washed with sodium sulphite solution (gr. 60 to 1 fl. oz.), after which the fungus can be easily scraped off. Infected patches may be painted daily with a 1 per cent. solution of gentian violet.

PYORRHŒA ALVEOLARIS; CHRONIC PERIODONTITIS

Ætiology and Pathology.—Stagnation of food mixed with pyogenic organisms between the teeth leads to inflammation of the edge of the gums—marginal gingivitis.

The attachment of the muco-periosteum to the neck of the tooth is destroyed, and a pocket develops between the tooth and the gum. The margin of the alveolar process is then slowly eroded as a result of rarefying osteitis, until it may finally be replaced by granulation tissue. Stagnation of infective material in the pocket leads to gradual extension of the disease and aggravation of the gingivitis. Pus is produced, the condition at this stage being commonly known as *pyorrhœa alveolaris*.

Symptoms—In marginal gingivitis the edge of the gum of one or more teeth is red and swollen and bleeds with abnormal ease when brushed, the first part to be affected being usually the interdental papillæ. When *pyorrhœa alveolaris* has developed, pockets are present round the teeth, and pus can generally be seen exuding from the edge of the gum. Even when none is seen on first examining the mouth, beads of pus appear if the edges of the gum are pressed. In chronic cases the teeth are often loose. Reflex salivation occurs, and an excessive quantity of mucus is secreted by the small mucous glands of the mouth. This is a common cause of aerophagy. The accumulation of decomposing food, debris and pus in the pockets round the teeth produces an unpleasant taste in the mouth, most marked on waking in the morning, and is a common cause of foul breath. There is no pain, and the slight discomfort which may be present is generally insufficient to induce the patient to consult a dentist.

Treatment—In early cases the disease can be arrested by scaling and treatment of the pockets with strong antiseptics. When the supporting bone has been destroyed to more than half the depth of the root, extraction is necessary. In intermediate cases the gum should be cut away in order to eradicate the pockets. The patient should then be given instructions regarding oral hygiene.

DENTAL CARIES

The immediate cause of dental caries is unknown, but two main theories have been put forward. The chemo-parasitic theory postulates that acid produced by bacterial fermentation of carbohydrates causes decalcification of the enamel and dentine, the acid being kept in contact with the tooth by a plaque of debris on its surface. The alternative theory is that the initial change is a degradation of the organic matrix of the enamel by bacterial enzymes and that the inorganic matrix subsequently disintegrates. It is generally agreed whichever theory is correct that caries is due to the activity of bacteria.

Symptoms—Caries teeth are tender, and their presence renders mastication painful. The patient therefore avoids using the affected teeth, and thus favours the deposit of tartar and the stagnation of food. If many teeth are affected the food is bolted, so that indigestion is likely to occur owing to insufficient mastication, quite apart from possible infection of the alimentary canal caused by swallowing septic material from the mouth. The irritation produced by the decomposition of stagnant food around the teeth gives rise to marginal gingivitis and *pyorrhœa alveolaris*. Oral sepsis produced in this way is of much more importance than that caused by the caries itself, as the quantity of decomposing material and bacteria swallowed from dental cavities is comparatively small, and no local absorption of toxins or bacteria can occur so long as the pulp cavity is not reached. When the latter becomes infected, absorption of toxins is likely to lead to enlargement of the cervical glands, especially in children, and the chronic inflammation produced in this way is a common precursor of tuberculous infection of the glands. Inflammation of the pulp spreads to the periodontal membrane and may finally produce an alveolar abscess.

Dental caries is the most common cause of toothache, and pain is often referred to various situations more or less remote from the teeth.

Prophylaxis—The incidence of caries can be significantly reduced by the addi-

tion of vitamin D, calcium and phosphorus to a diet which is deficient in these substances, and the improved dentition of British children in the post-war years was attributed to the war-time provision of extra milk and vitamin D. Calcium carbonate was also added to the flour and the vitamin D content of margarine was increased. Refinement of flour is detrimental because it removes phosphorus and increases the content of phytic acid, a substance which interferes with the absorption of calcium. Caries is especially prevalent in regions where there is a natural deficiency of fluorine and it has been shown that the artificial fluoridation of drinking water, to an optimal value of 1.0 to 1.2 parts per million significantly reduces its incidence. Concentrations above this level are liable to cause mottling of the teeth. Fluorides can also be applied directly to the teeth, and four applications of a 2 per cent. solution of sodium fluoride at weekly intervals will usually reduce the amount if not entirely prevent the onset of caries.

Oral hygiene.—The teeth should be brushed regularly vertically from the gums to the teeth, and wooden tooth-picks used to clear and massage the gum spaces between them. Tincture of iodine may be applied on a wisp of wool on the end of the tooth-pick. The mouth should be well rinsed after meals. Ideally, sugar and sticky carbohydrates should be eliminated from the diet, and they should be replaced by natural unrefined vegetable foods.

Treatment.—This is the province of the dental surgeon. Removal of all the milk teeth in children may cause narrowing of the dental arch and consequent crowding of the permanent teeth, but this can be easily remedied by treatment, whereas the septic condition of the mouth caused by extensive caries may lead to permanent ill results.

APICAL INFECTION

Ætiology.—Infection of the apex of the root of a tooth can occur only if the pulp is dead, except in rare cases of extensive caries.

Symptoms.—Apical infection may be acute or chronic. In the former an alveolar abscess forms, which gives rise to the usual symptoms and signs of inflammation. Chronic apical infection, on the other hand, frequently gives rise to no pain or discomfort, and no signs recognisable on ordinary examination. It can then be recognised only in a good radiograph.

Treatment.—In cases of moderate severity the pulp canal should be opened and sterilised by antiseptics, e.g. ammoniacal silver nitrate followed by formalin, or penicillin 25,000 units per ml., or ionisation with zinc chloride, or diathermy applied down the root canal, and the root should be filled to its apex with an impervious material. In more advanced cases, and in all in which secondary symptoms are present, extraction should be performed without delay and the socket should be curetted.

HALITOSIS (BAD BREATH)

An offensive odour to the breath is mainly of importance because it may give rise to serious feelings of inferiority and self-consciousness if the sufferer is made aware of his complaint. In most cases of halitosis the individual is, in fact, unconscious of any bad smell—on the contrary, when he is continually complaining of his breath it is often found to be due to an obsessional neurosis and that he has actually no odour at any time. A pungent heavy breath is frequently due to bad teeth, decaying food in dental cavities, pyorrhœa, or to cheesy putrefactive material in the crypts of the tonsils. Ozœna (see p. 956) is a further local cause, as may, rarely, be infected accessory nasal sinuses. Decaying material on the back of the tongue may become

offensive and pulmonary conditions, such as lung abscess or bronchiectasis are other causes

Hepatic or intestinal causes of halitosis can less easily be demonstrated and, though it is popularly believed that chronic constipation may be a cause, this is, in fact, very doubtful. The odour of garlic when swallowed in capsules may remain in the bile after it has disappeared both from the breath and the intestine, and it seems probable that liver dysfunction may play a part in some cases of halitosis. The sulphur smelling mercaptan may be smelt strongly in the breath in cases of hepatic necrosis.

Treatment.—Some cases of unexplained halitosis are improved by much reducing the amount of fats in the diet. Purgatives are of little use, though saline laxatives are often advocated. Attention must be paid to the mouth, teeth, throat and nose. Chlorophyll tablets taken orally will often remove the odour completely and may be ordered freely without ill effects.

DISEASES OF THE SALIVARY GLANDS

PTYALISM

Ætiology.—The flow of saliva is increased by reflexes originating in the mouth and also in more distant situations. Thus all pathological conditions in the mouth and its neighbourhood, such as stomatitis, epithelioma of the tongue and carious teeth, especially if associated with pain, are accompanied by salivation. Trigeminal neuralgia, whatever its cause, is frequently associated with a reflex flow of saliva. Mechanical irritation of the œsophagus caused by the passage of a tube into the stomach or by the impaction of a foreign body causes salivation, which is a common symptom in achalasia of the cardia and in simple and malignant ulceration of the œsophagus. Reflex salivation is the cause of waterbrash associated with the hyperchlorhydria of duodenal ulcer.

The salivation which may occur during menstruation and in the early months of pregnancy is also probably reflex in origin. Salivation is a common and sometimes very distressing symptom of paralysis agitans and post-encephalitic Parkinsonism. Ptyalism may result from excessive smoking. It is also caused by the specific stimulating action of certain drugs, such as pilocarpine, and by drugs such as the iodides and mercury, which are partially excreted by the salivary glands.

Symptoms.—Every time saliva is swallowed air passes with it into the stomach. In neurotic individuals a spitting or swallowing tic may develop, the latter is always accompanied by aerophagy and the patient consequently complains of severe flatulence with excessive belching (p. 566).

Treatment.—In order to cure ptyalism the primary cause must be discovered and removed. As purely symptomatic treatment, belladonna should be given 5 minims of the tincture, taken three times a day, half an hour before meals may be sufficient, but much larger doses are often required. The drug has the additional advantage of diminishing the secretion of gastric juice when gastric hypersecretion is also present.

XEROSTOMIA

Ætiology.—The dry mouth, which is constantly present in fevers, is due mainly to deficiency in the physical, chemical and mechanical stimuli to salivary secretion. The associated toxæmia probably also exerts some direct inhibitory action on the gland-cells. Depressing emotions and the loss or perversion of taste, which may occur when the tongue is furred, result in diminution in the physical secretion. The paralysis of the secretory nerve-endings produced by belladonna, stramonium

and their alkaloids sets the limit to the dose of these drugs which can be administered. The secretion of saliva is also diminished when excessive quantities of fluid are lost by other channels, as in severe diarrhoea. Diseases of the salivary glands themselves, such as mumps, result in diminished secretion. Severe xerostomia occasionally develops without any obvious cause. A dry mouth is also a common result of sleeping with the mouth open.

Symptoms.—Deficient secretion of saliva causes the mouth to become dry and septic, as particles of food remain between the teeth, where they undergo bacterial decomposition. The tongue is furred and dry, and there is often an unpleasant taste in the mouth. It is difficult to chew food sufficiently, and the appetite is impaired as a result of the condition of the mouth and the difficulty in tasting. The insufficiently chewed food is likely to irritate the stomach. In severe cases dysphagia occurs and speech becomes difficult. The loss of the digestion of starch by the ptyalin of the saliva is of no importance owing to the amylolytic activity of the pancreatic juice.

Treatment.—A diet should be chosen which stimulates the flow of saliva; acids are most active, then salt and bitters, whilst sweet substances have very little action. The food should be given in as appetising a form as possible and masticated very thoroughly. The taste of a bitter mixture taken immediately before meals may directly stimulate the flow of saliva, and pilocarpine may be tried, but it is rarely of much use, as a dose sufficiently large to increase the flow of saliva generally produces unpleasant symptoms, such as excessive sweating. It is, however, valuable in the treatment of paralysis agitans and post-encephalitic Parkinsonism, as it counteracts the xerostomia (and also the paralysis of the intrinsic eye muscles) often caused by hyoscine and stramonium, without diminishing their effect on the tremor of paralysis agitans and the rigidity following encephalitis. Great care should be taken to keep the teeth clean, and the mouth should be washed after each meal.

SPECIFIC PAROTITIS (MUMPS)—(see p. 174)

PAROTITIS

Ætiology.—Parotitis is usually due to infection ascending Stensen's duct from the mouth. This is particularly apt to occur in the acute parotitis that not infrequently follows operations on the alimentary tract when the mouth has become septic owing to dehydration, the absence of chewing and normal salivation. It may develop secondarily to obstruction from a stone in Stensen's duct, or in the dry mouth of Sjögren's syndrome or diabetes mellitus. It may also follow trauma of Stensen's duct by ill-fitting dentures. Subacute parotitis, which is often recurrent, may also occur in persons with apparently healthy mouths. The infection may be limited to Stensen's duct, when it is referred to as sialodochitis, or it may spread from the ducts to the tissues of the gland. Blood-stream infection may also take place. The subacute recurrent type of infection is relatively common in children and occurs more frequently in women than in men. In children recurrent attacks tend to become less severe as adolescence is reached and usually clear up before adult life.

Symptoms.—In acute parotitis following operation one or both glands may be affected. The glands are enlarged and tender, the skin over them reddened, shiny and oedematous. In severe cases, suppuration takes place, the neighbouring lymphatic glands enlarge, the temperature is high and severe constitutional symptoms are present. The mouth is dry and difficult to keep clean; the tongue is covered with a thick fur. The mouth of Stensen's duct is everted and forms a small, red nodule from which a bead of pus can usually be squeezed. In most cases the inflammation

subsides with antibiotic treatment, abscess formation may occur, rarely the condition becomes chronic, the parotid glands remain permanently enlarged and excrete a reduced quantity of saliva.

In the subacute form swelling of one or both glands may occur on a single occasion or repeatedly at intervals of weeks or months, sometimes over a period of many years. The swelling usually lasts for several days but may persist for months. Fluctuation in the size of the swelling takes place, an increase usually accompanying or following mastication. The inflamed gland is tender to pressure and the overlying skin may be reddened and hot. Firm pressure over the gland often causes expulsion of pus or turbid saliva from the reddened orifice of Stensen's duct. The submandibular glands may be affected in the same way, either by themselves or in association with parotid swellings. In these patients radiographic examination of the ducts after injection of lipiodol frequently shows beadlike dilatation of the terminal acini, or there may be irregular dilatation of the main duct and its branches. The condition must be differentiated from leukaemia with infiltration of the parotid and submandibular glands and from uveoparotitis or Heerfordt's disease which is a special form of sarcoidosis.

Microscopical examination of the parotid saliva shows degenerated leucocytes, epithelial cell debris and organisms. In acute parotitis *Staphylococcus aureus* is the organism usually responsible, while in the subacute and recurrent forms *Streptococcus viridans* and *pneumococcus* are commonly found.

Treatment.—In acute parotitis treatment with penicillin in full doses usually leads to resolution. Hot fomentations or application of an electric pad may ease the pain of the swollen gland. Mouth washes may be used and steps should be taken to overcome dehydration and to deal with local conditions in the mouth if these exist. If abscess formation has occurred incision of the gland will be necessary.

In subacute cases penicillin is also useful, local application of heat to relieve the pain and chewing gum to assist drainage. When the active phase has subsided short wave diathermy is often helpful. In long standing cases with chronic infection and persistent swelling deep X ray therapy is sometimes justified, but this treatment which destroys the secretory mechanism of the gland and induces fibrosis should never be employed in children whose facial bones are still developing, since in such cases it may interfere with the growth of the mandible.

NON-INFECTIVE RECURRENT SWELLING OF THE PAROTID GLANDS

Ætiology.—This condition may occur at all ages. The cause is often uncertain, but the frequent association with allergic conditions in the patient himself or in his relatives has led to the suggestion that an allergic process is responsible. A number of cases have been described in which this pathogenesis has been demonstrated beyond doubt.

Symptoms.—Eating may precipitate attacks especially when the food is so character, and in some patients the parotid glands become swollen whenever food is taken over a period of many years. In others the swelling is definitely associated with the eating of certain foods to which the patient is specifically sensitive. The swellings are more often bilateral than unilateral. They develop rapidly and are present for a short time only, often subsiding within half an hour and seldom persisting for more than 24 hours. Single isolated attacks may occur, but owing to their brief duration and the absence of after-effects they are seldom seen, and cases presenting themselves for treatment are usually recurrent. Signs of inflammation are absent, the parotid saliva contains no pus and the swellings are seldom painful.

In most cases secretion can be expelled from the parotid duct by pressure during

the attack. Globules of jelly-like mucus obstructing Stensen's duct may first be forced out, followed by 2 or 3 ml. of clear saliva. It is in this type of case that eosinophil cells have been observed both in the mucous plugs and in the pent-up secretion. This is sterile and contains no pus, but secondary infection may supervene in patients in whom swellings have recurred over a long period. In early cases saliva may be difficult to obtain.

Sialography may show gross fusiform dilatation of the main and branch ducts in long-standing cases; in others the appearance is similar to that seen in infective parotitis, with bead-like terminal dilatations. In early cases the appearance may be normal.

Treatment.—Massage over the gland is of value, especially when mucous obstruction is present. In some cases injection of adrenaline subcutaneously leads to subsidence of the swelling. If specific foods cause the swelling, these must be avoided.

THOMAS HUNT

DISEASES OF THE TONSILS

ACUTE TONSILLITIS

Tonsillitis has been classified as superficial, follicular or lacunar, and parenchymatous, according to the degree in which the various parts of the gland bear the brunt of the inflammation; the distinction, however, is not a definite one, as the entire organ is necessarily inflamed.

Ætiology.—The disease is rare in children below the age of 3, and after middle age; and it is commonest in spring and autumn. It is predisposed to by general ill health, overwork and a polluted atmosphere; and the infection may be carried by water or milk. Cross infection in hospital wards, dormitories and classrooms is often an important factor in spreading the disease. It occurs as a regular symptom of scarlet fever and measles. There is a connection between rheumatism and tonsillitis, and it was formerly believed that tonsillitis was of rheumatic origin; but it is now generally recognised that both acute rheumatic fever and chronic rheumatic pains in joints and muscles are often caused by absorption from infected tonsils. Unhealthy conditions of the teeth or tonsils predispose to further attacks by causing adhesions in the crypts or supratonsillar fossæ, thus promoting the retention of secretion; previous incomplete removal acts in the same way. The usual bacterial cause is a hæmolytic streptococcus (*Str. pyogenes*) of Lancefield's Group A.

Symptoms.—The symptoms are those of a feverish attack, together with a sore throat; the former often appears before the latter, and only examination of the throat reveals the cause of the disturbance. The temperature may rise to 103° or 105° F., and there is a variable degree of malaise, backache, headache and pain in the limbs. The soreness of the throat radiates to the ear, and is increased by attempts to swallow; the voice becomes thick, the breath foul and the submaxillary and upper cervical glands are tender and swollen.

The tonsils are swollen, and their purple-red colour extends to the pharynx, palate and uvula—the latter frequently being œdematous. In the follicular type the surface of the tonsils is spotted over with yellowish masses of secretion which have exuded from the crypts; sometimes this secretion becomes confluent on the tonsils, it is soft and readily wiped away. The tongue is coated, and the fauces covered with tenacious mucus. There is usually constipation, and the urine is scanty and high-coloured, but not ordinarily albuminous. Albuminuria is, however, an occasional complication, as are pericarditis, endocarditis and suppurative otitis media.

Diagnosis.—The diagnosis from diphtheria is important, and sometimes difficult. The latter is more gradual and asthenic in onset, with less pain, less fever and a more rapid pulse, and the urine frequently contains albumin. The membrane of diphtheria is greyish white rather than yellowish, and frequently spreads to the pillars and soft palate, though it may on occasions be confined to a very small area. The exudation of tonsillitis rarely spreads, and never to any great extent, beyond the surface of the tonsils. The diphtheritic membrane is adherent and, when detached, leaves a raw bleeding surface, while that of tonsillitis is readily removed and more often discrete. In cases of doubt a bacteriological examination should always be made, and an injection of antitoxin should be given while waiting for the result.

Treatment.—Complete bed rest is the most important step in treatment. If, as is so often the case, the patient is constipated a suitable aperient should be prescribed. The time-honoured custom of applying hot fomentations to the neck merely irritates and tires a sick patient whose greatest need is rest.

The severely ill patient cannot gargle, and it is foolish to make him try; he will, however, derive some comfort from alkaline mouth washes. Lozenges are often demanded by the patient or his relatives and it may be well to accede to these demands, trochiscus phenolis is harmless and has a certain local analgesic effect. Penicillin lozenges are sometimes of value, but their routine use is not recommended because severe stomatitis may result. Internally aspirin is useful, the following, shaken with an equal quantity of water, may be used as a mouthwash and then swallowed:

Acidi acetyl-salicylici	gr. 10
Pulv. Tragacanthæ Co	gr. 10
Aquæ	to 1 oz.

Feeding is often difficult and the patient must be encouraged to take as much nourishment as his dysphagia permits. Semi-solids are usually easier to swallow than liquids and there is scope for ingenuity in provision of a suitable diet. Junket, meat jellies and thick unseasoned soups are acceptable.

There is little more to be said about the treatment of mild cases. In severe cases sulphonamides, penicillin, or even both, will be indicated. It is important to realise that the earlier a sulphonamide is given the more likely it is to succeed. Dosage must be sufficient to maintain an efficient blood level for 5 days even if the temperature settles early. A generous fluid intake is essential. Penicillin, when prescribed, must be given in full doses for 5 days. It is usually not worth while to take cultures and test organisms for sensitivity to antibiotics since Group A hæmolytic streptococci are always penicillin-sensitive.

There is yet no evidence suggesting that other more recently discovered antibiotics are better than penicillin.

PERITONSILLAR ABSCESS OR QUINSY

Ætiology.—This condition can be defined as inflammation with pus formation in the loose areolar tissue *outside* the tonsil. Infection in the supratonsillar fossa or in the depth of a crypt bursts through the capsule. This process is favoured by adhesions obstructing the mouth of the supratonsillar fossa or the crypts, wherefore previous attacks of tonsillitis and imperfect surgical removal are predisposing causes. The abscess is usually situated above and external to the tonsil, but in rare cases is behind it.

Symptoms.—The affection is unilateral; but sometimes the opposite side is attacked as the first recovers. It begins with a feeling of malaise, fever, often a rigor, and severe pain radiating from one side of the throat up to the ear and into the neck.

the cervical glands are enlarged and tender, and the neck stiff. Dysphagia is intense, the tongue thickly coated, and the breath foul. The mouth cannot be opened widely, and a good light is required for examination, when the typical large deep-red swelling is to be seen bulging one side of the soft palate. Pus forms in 2 to 4 days and, if left alone, will eventually burst through the supratonsillar fossa or occasionally through the soft palate; relief is then immediate, but occasionally the opening closes prematurely and the abscess refills. A much less acute, almost insidious, form of quinsy is sometimes seen when a patient suffering from acute tonsillitis has received sulphonamide treatment too late and in ineffectual doses.

Diagnosis.—Occasionally diphtheria simulates quinsy when swelling is disproportionately great and when only a tiny area of diphtheritic membrane is present. Malignant disease of the tonsil and tonsillar stone have been mistaken for quinsy.

Complications.—Although one of the most painful and distressing of acute diseases, complications are uncommon, and death is very rare; it has occurred from rupture of the abscess, and inspiration of the pus, during sleep. Severe hæmorrhage may take place after spontaneous or surgical evacuation of the abscess when, as the blood may come from the internal carotid or from a branch of the external carotid artery, ligation of the common carotid is called for. Suppuration of the cervical glands is a rare complication, as are pneumonia, septicæmia and pyæmia.

Treatment.—The general treatment is the same as that of severe acute tonsillitis, and the pain sometimes calls for an occasional injection of morphine. In the early stage, before pus has formed (peri-tonsillitis), systemic penicillin may be given in full doses with good prospects of aborting abscess formation. The treatment should be continued for 5 days even if improvement is obvious. If pain and trismus persist beyond the third day it must be assumed that pus has formed and the abscess should be opened without delay. Even experienced physicians often find difficulty in making a confident diagnosis of pus formation, in such cases it is usually wise to continue penicillin treatment for 24 hours and re-examine the throat on the following day.

The procedure of opening a quinsy is not always easy for the patient will not be able to open his mouth wide and a good light is essential. An adult should not be given an anæsthetic, though the throat may be sprayed with cocaine 5 per cent.; an alternative plan is to allow him to suck an amethocaine hydrochloride (Dedocain) lozenge. He must be seated bolt upright and his head rigidly supported. A thin-bladed scalpel adequately guarded is thrust into the most prominent part of the swelling, the cutting edge should lie upwards and the blade held in the sagittal plane. The scalpel should not be introduced deeper than $\frac{1}{2}$ inch. Whether or not pus is struck at once a sinus forceps is introduced into the wound and opened widely to assist evacuation. Children must be given an anæsthetic but the mouth gag must be introduced before induction and a sucker must be at hand lest the abscess bursts spontaneously before full anæsthesia is obtained. The patient's head must be extended (chin to ceiling) before the incision is made.

When the acute illness is over the patient must be told that the tonsils should be removed to prevent recurrence. It is very unwise to operate until at least a month has elapsed.

CHRONIC TONSILLITIS

Many attempts have been made to classify chronic tonsillitis and much unnecessary confusion has arisen. Pathologists disagree about the definition of chronic infection whilst physicians have accepted clinical distinctions which are often non-existent. It has been the custom for years to speak of chronic parenchymatous tonsillitis and chronic follicular tonsillitis; in the former there is parenchymatous hyperplasia and overgrowth of lymphoid tissue, whilst in the latter crypts become

distended with epithelial debris and pus. It is easier and much more logical to refer to chronic tonsillitis in the knowledge that the picture presented may vary. If chronic infection is present it matters little whether the tonsils themselves are large from parenchymatous hyperplasia or small and fibrotic with pus leaking from distended crypts.

Accepting this simplification makes it possible to refer to enlarged tonsils without inferring infection. Many healthy children have large tonsils which never give rise to trouble and are best left alone. It is proposed to refer to the problem of chronic tonsillitis as it affects children and adults separately.

CHRONIC TONSILLITIS IN CHILDREN

Infected tonsils in children are usually enlarged and associated with enlarged adenoids, though gross hypertrophy of adenoids may exist when tonsils are small. Healthy tonsils and adenoids tend to atrophy at puberty and hypertrophy seldom takes place *de novo* after that age.

Ætiology.—The condition occurs chiefly in children between the ages of 4 and 14 and, as a rule, results from repeated acute attacks. The first throat infection may have arisen as a manifestation of scarlet fever or measles. Unsuspected infection of the maxillary antra may lead to chronic tonsillitis.

Symptoms.—The symptoms are often overshadowed by those primarily due to enlarged adenoids, mouth breathing, toneless speech, snoring, recurrent otitis media and deafness of varying severity. Between recurrent attacks children seldom complain of sore throat. Cervical lymph nodes are easily palpable and sometimes become visibly enlarged, suppuration in the glands is now uncommon. It is well to remember that in some cases the enlarged nodes are tuberculous.

The objective appearances are very variable, and it is extremely difficult to estimate the healthiness of a tonsil by inspection. Slightly enlarged tonsils may be prominent and may readily meet on gagging, while big tonsils are often largely buried in the palate or hidden beneath the plica triangularis—in which case a bulging can be seen at the side of the soft palate corresponding to the site of the upper pole.

Treatment.—It is important to realise that no local treatment to chronically infected tonsils is of value. Pains, gargles and lozenges may have to be prescribed but only to ease the minds of anxious parents. Recognition and treatment of maxillary sinusitis is important.

When it is considered that the degree of chronic infection is not severe enough to warrant surgical removal, an open air life in the country or at the seaside can be advised if domestic circumstances permit. The well-disciplined child who is sent to bed at reasonable hours does better than the spoiled child.

Unhealthy tonsils should be removed when there have been repeated attacks of tonsillitis, after a quinsy, when there is chronic enlargement of the cervical glands and when rheumatic fever or chorea has occurred. Definitely unhealthy tonsils should also be removed in cases of chronic or recurrent otitis media, whilst recognising the even more important role of enlarged adenoids in the causation of this complication. When chronic cervical adenitis is present, and is not due to some other obvious cause, such as pediculosis or dental caries, the tonsils should be removed whether they appear diseased or not, in these cases about one third of the tonsils are tuberculous, and this latent tuberculous cannot be recognised by inspection, many of these tonsils indeed being quite small.

The reader is referred to surgical works for details of the operation, but it may be said here that, if a tonsil requires removal, it must be removed completely in its capsule, for the deeper portion of a diseased tonsil is quite as unhealthy as the superficial, trouble in the remaining portion is very common, and the previous operation only adds to the surgeon's difficulties.

CHRONIC TONSILLITIS IN ADULTS

In older subjects, when fibrosis has followed hypertrophy, the stenosed crypts become filled with yellowish-white caseous masses. The patient complains of an offensive taste, foul breath, often of recurrent attacks of sore throat and of gastric disturbances. Not infrequently various forms of chronic toxæmia, such as fibrositis or arthritis, are induced by absorption from these septic foci. In many cases the tonsils are quite small; they may look healthy, but pus can be squeezed out of the crypts on applying pressure at the anterior pillar by means of a flat instrument.

Treatment.—The treatment in the more marked cases is removal. There are, however, a good many patients who have only a few unhealthy crypts in the tonsils; such patients may be taught to empty these crypts by pressure on the anterior faucial pillars with the handle of a spoon. The mouths of the crypts may be painted with guaiacol 4 per cent. in glycerin.

VINCENT'S ANGINA

Ætiology.—This affection is believed to be due to two organisms, the fusiform bacillus and spirochaete of Vincent growing in symbiosis; these organisms may be found in many ulcerative conditions of the mouth and throat, but their constant presence in this affection points to their specific character. Affection of the throat is frequently secondary to periodontal infection of the gums. It occurs especially in debilitated persons and under insanitary conditions and, though rather rare in civil life, was common during the War of 1914–1918 and the War of 1939–1945.

Symptoms.—The attack begins insidiously, with malaise, general pains and a temperature of 100° to 101° F. The pain in the throat is often slight but in some cases may be severe, but the glands on the affected side become enlarged and tender, and the breath is characteristically offensive.

There is superficial ulceration, which commonly involves tonsils or fauces but may affect the inner surface of cheek, pharyngeal wall or larynx. The ulcers vary in size; their base is covered with a yellowish-grey pseudo-membrane which is not easily detached, and there is marked hyperæmia around the edges. In rare cases the pseudo-membrane is replaced by a heaped-up irregular slough. By the end of a week the membrane ceases to form, and the ulcer begins to heal.

Complications are very rare.

Diagnosis.—The disease is particularly interesting by reason of its liability to imitate diphtheria in its early stage, and syphilitic ulceration later. In both cases the discovery of numerous spirilla and fusiform bacilli in smear-preparations—they are difficult to cultivate—will help the physician to the correct diagnosis; but these organisms may also be found in syphilitic ulcers, and the Wassermann reaction is occasionally positive in Vincent's angina. The subacute onset, the raised temperature and the tenderness of the glands aid the differentiation from syphilis; and from diphtheria the milder constitutional symptoms, the soft friable character of the membrane and the absence of the diphtheria bacillus. Cases of non-specific superficial ulceration involving tonsil fauces and inner surface of cheek are not unduly rare. One form occurs as a result of semi-starvation or a grossly unbalanced diet. A second form remains entirely unexplained, it is common in women and no specific organism or virus has been discovered. Patients suffering from this mysterious type of ulceration almost always have some unresolved psychological worry. Physicians should be alive to the fact that ulcerative lesions can also occur in the course of agranulocytic angina, leukaemia and glandular fever.

Prognosis.—Death hardly ever occurs.

Treatment.—The ulcerated areas should be cleaned with hydrogen peroxide, after which topical applications, such as liquor arsenicalis and vinum ipecacuanha in equal parts, or neoarsphenamine in the strength of gr. 20 to the oz. of glycenn, may be used. These should be firmly applied on a swab, with due regard to their poisonous nature.

Ascorbic acid and vitamin B complex are valuable, particularly in the treatment of recurrent cases. Dental supervision is important.

The causal organisms are not easy to culture so that bacteriological tests for sensitivity to modern antibiotics are unreliable. It is, however, recognised that the use of systemic penicillin is amply justified by results. Penicillin lozenges are best avoided because their use is too often followed by stomatitis.

W. I. DAGGETT

DISEASES OF THE PHARYNX

DIVERTICULA (see p. 546)

ACUTE CATARRHAL PHARYNGITIS

This is not a very well-defined affection, and is usually accompanied by acute rhinitis on the one hand, and by laryngitis on the other, the tonsils also often participate in the inflammation.

Ætiology.—The affection is generally the result of coryza, and it is a feature of various acute infectious fevers, such as measles, German measles, scarlet fever, influenza and typhoid.

Symptoms.—The discomfort varies from a tickling sensation, or the feeling of a lump in the throat, to severe dysphagia. The voice is husky and thick, and the cervical glands tender and somewhat enlarged. There is slight fever and general malaise.

The pharynx is to a varying degree red and swollen, especially at the sides behind the posterior faucial pillars, where the swelling forms the so-called "lateral bands". The palate is swollen and relaxed and the uvula elongated. The posterior wall is often covered by a film of tenacious mucus.

Treatment.—The patient should stay in a warm room and avoid the irritation of smoking, talking, alcohol or irritating foods. Aspirin, or sodium salicylate, is helpful and it is important to treat any primary cause.

ACUTE SEPTIC PHARYNGITIS

This term includes a series of severe infective inflammations, cedematous, phlegmonous and gangrenous pharyngitis and laryngitis, and Ludwig's angina. Any classification must necessarily be a clinical one, based on the severity of the symptoms and their localisation, for they can be produced by a variety of micro-organisms though they are usually caused by a streptococcus. These severe inflammations are fortunately uncommon, and most often, though by no means invariably, occur in debilitated or alcoholic persons.

Symptoms.—These vary greatly with the severity of the infection, which ranges from a mild inflammation to the most severe septic intoxication. They include malaise, sore throat, dysphagia, hoarseness and dyspnoea. The temperature in some cases rises to 105° or 106° F., but in many of the worst cases it is hardly raised at all, and may be subnormal. Pleurisy, pneumonia and pericarditis may ensue or death may result from asphyxia, but the worst cases die from general toxæmia and heart failure, even within 24 hours of the onset of the disease.

The objective appearances, also, are very variable. The pharynx and palate are of a deep purplish red, and there may be sloughy pseudomembraneous patches. The entire mucosa may be enormously swollen, and the oedema may involve the upper aperture of the larynx and produce asphyxia. The sublingual region is sometimes occupied by a peculiar brawny swelling, of a hardness like wood, which spreads downwards into the neck to a variable extent, and is known as Ludwig's angina.

Treatment.—The patient must be in bed and well nursed, and every care must be used to ensure that he takes as much nourishment as possible. Sulphonamides and antibiotics must be the mainstay of treatment. Adults should receive 60,000 units of penicillin 3-hourly, and this may be combined with full doses of a suitable sulphonamide. A high fluid intake must be assured. Oedema of the glottis may call for emergency tracheotomy. For Ludwig's angina it is now only rarely necessary to make an incision deeply into the neck in the hope of striking pus; the swelling will either subside or a fluctuating abscess will become apparent.

RETRO-PHARYNGEAL ABSCESS

There are two forms—(1) Acute, and (2) Chronic.

1. The acute form occurs in children up to the age of 3 or 4, but is far more frequently met with in the first 12 months. It is due to suppuration in the pre-vertebral glands situated behind the posterior pharyngeal wall; these glands disappear in later life. The abscess is secondary to nasal, naso-pharyngeal or tonsillar infection and may occur during the course of an infectious fever.

Though rare, the condition is an important one, for it may easily remain unrecognised in a young infant, and may be fatal if the abscess is left unopened. The symptoms are fever and restlessness, a hoarse cry and croupy cough, with difficulty in swallowing and dyspnoea. Such symptoms should arouse a suspicion of retro-pharyngeal abscess, which may be seen on inspection as a rounded swelling of the posterior pharyngeal wall. The abscess is often very large, and must be freely opened in such a way as to avoid aspiration of the pus, without an anæsthetic, and with the child firmly held, either on the side with the face directed somewhat downwards, or on the back with the head hanging almost vertically. A suction apparatus must be at hand. Recovery is rapid, and no after-treatment is required beyond attention to the enfeebled general health.

2. The chronic form, also, is found most frequently in children, but generally after the third year. It is of tuberculous origin, and is due either to tuberculosis of the prevertebral glands, or to caries of the cervical spine. The latter should be carefully excluded, for this abscess should not be opened through the mouth, as secondary infection of the diseased bone is likely to occur. The chronic glandular abscess, however, may be successfully opened by this route, though some surgeons prefer to treat all chronic cases by an incision beyond the sterno-mastoid.

Ætiology.—Chronic pharyngitis is usually secondary to chronic infection in the nasal sinuses, tonsils and teeth. It is aggravated by mouth-breathing, excessive smoking and over-indulgence in alcohol.

Symptoms.—Discomfort may take the form of aching, fullness or feeling of a lump, a hair or a pricking. The voice has a dead tone, and there is usually much hawking and frequent swallowing. The sufferer often becomes depressed, and fears that he has cancer of the throat. The unpleasant sensations are markedly lessened after a meal.

The mucosa of the pharynx and palate is thickened, and there is a loss of the finer modelling of the faucial pillars; the uvula is elongated, often slightly edematous at its edges and tip, and fails to retract on phonation. The posterior wall is covered by a film of mucus, which puckers up and becomes more obvious on touching it with a probe or swab. The wall of the pharynx is traversed by enlarged venules, and sometimes it is set with slightly raised pink lenticular nodules of lymphoid tissue, constituting a variety known as *granular pharyngitis*. In other cases two elongated masses of lymphoid tissue appear behind and parallel to the posterior pillars; these are the "lateral bands", and this form is called *lateral pharyngitis*. Patients suffering from atrophic rhinitis may complain of dryness of the throat; the posterior pharyngeal wall presents a glazed dessicated appearance, sometimes alluded to as *pharyngitis sicca*.

Treatment.—The most important part of the treatment consists in the detection and alleviation of the cause, and should begin with a careful examination of the nasal passages. Cases of pharyngeal hyperæsthesia without obvious local changes are often harmed, rather than helped, by local treatment which directs attention to their trouble. Tobacco should be given up, and alcohol in concentrated forms, indeed the latter should be abandoned completely in plethoric patients; condiments and highly seasoned food should be avoided. This type of patient is benefited by a morning dose of sulphate of soda or magnesia, a teaspoonful in a glass of hot water while dressing, or by one of the natural mineral waters. When the pharynx is dry, or covered with tenacious mucus, an expectorant mixture gives relief, such as tinctura ipecacuanhæ, min. 12, vinum antimoniale, min. 5, potassium iodide, gr. 3, syrup of tolu, min. 60, water, 1 fl. oz., three times a day. The throat may be sprayed with a warm alkaline saline lotion, or protargol 10 per cent. Of local applications in the form of paints, 10 per cent. protargol is the most generally useful, 4 per cent. guaiacol in glycerin is also well tolerated. In cases presenting heaped-up inflamed patches of lymphoid tissue on the posterior pharyngeal wall, the galvano cautery may be of value, but it must be used lightly so that subsequent scarring is minimal. Many patients suffering from this complaint are intelligent yet introspective and neurotic, and alcoholic indulgence makes them impatient and intolerant. It is difficult to explain that constant hawking makes them worse, and the physician's most common mistake is to fix his patient's mind on the throat by over-treatment.

KERATOSIS PHARYNGIS

In this condition a number of sharply defined white or yellow spikes project from the surface of the tonsils; they also occur, though less profusely, scattered over the lingual and naso-pharyngeal tonsils and on any lymphoid granules in the pharynx. They occur at any age after childhood and the causation is unknown. The projections consist of heaped-up epithelium and detritus containing numerous micro-organisms of the kind ordinarily present in the mouth. On microscopical examination branching fungus mycelium can usually be demonstrated. They sometimes disappear quickly, in other cases they remain for many months, or they may recur. They produce no symptoms, or at most a slight discomfort, and are of interest chiefly

because they are frequently mistaken for the exudation of chronic follicular tonsillitis. Once seen they can, however, be recognised at a glance, for they are hard and adherent, discrete and prominent, and occur beyond the limits of the tonsils, on the pharynx and base of the tongue. They are usually discovered accidentally by the patient, who is naturally alarmed at their appearance. They are quite harmless, and local treatment is useless for they are removed with difficulty and usually recur, it is wise to reassure the patient by telling him these facts and, if any treatment be required, to trust to attention to the general health, a holiday and change of air.

W I DAGGETT

DISEASES OF THE ŒSOPHAGUS

THE NORMAL ŒSOPHAGUS

The act of swallowing occurs in four stages. The first consists in the voluntary propulsion of food from the mouth to the pharynx. The second is set in action by a reflex arising from the contact of food with the posterior wall of the pharynx, which leads to closure of the passages leading to the mouth, nose and larynx together with a rapid peristaltic wave travelling down the constrictors of the pharynx, which is followed by the opening of the hitherto closed pharyngo-œsophageal sphincter formed by the lower division of the inferior constrictor. The third stage consists in the propulsion of the bolus by a peristaltic wave down the œsophagus till it reaches the closed cardiac sphincter, the active opening of which constitutes the fourth and final stage of deglutition. The "suction effect" due to active relaxation of the œsophagus in front of the bolus certainly plays some part in swallowing in addition to the peristaltic contraction from behind.

DYSPHAGIA

Dysphagia, or difficulty in swallowing, is generally the first symptom in diseases of the œsophagus. Owing to the fixed position of the œsophagus localisation of abnormal sensations is very accurate, and a patient generally points to the exact level of obstruction. In some cases, however, reflex spasm of the pharyngo-œsophageal sphincter occurs in association with lower œsophageal lesions, so that the patient experiences difficulty in initiating the act of swallowing as well as feeling the obstruction in the œsophagus caused by the primary disease.

The causes of dysphagia can best be considered according to whether the difficulty is experienced at the upper extremity, near the middle or at the lower extremity of the œsophagus, the last is the most common.

(a) *Pharyngo-œsophageal dysphagia*—This is most commonly found in the Plummer-Vinson syndrome. In rare cases it is hysterical and it may also occur in various organic nervous diseases. Upper dysphagia may be caused by carcinoma, especially in women, and by a pharyngeal pouch, especially in old men.

(b) *Mid-œsophageal dysphagia*—This is almost always caused by carcinoma. External pressure by an aneurysm or mediastinal tumour rarely causes dysphagia.

(c) *Lower œsophageal dysphagia*—Dysphagia at the lower end of the œsophagus is most frequently caused by achalasia of the cardia and by carcinoma of the œsophagus. Next most frequent is the dysphagia caused by spasm secondary to peptic œsophagitis and œsophageal ulcer, especially in the presence of hiatus hernia and by carcinoma of the fundus of the stomach. Lastly, the dysphagia may be due to cicatricial stenosis secondary to peptic ulcer or to the phlegmonous œsophagitis resulting from the swallowing of boiling water or corrosive poisons.

HYSTERICAL DYSPHAGIA

Theoretically there is no reason why hysterical dysphagia should not develop in the form of paralysis or inco-ordination of the voluntary muscles concerned in the first two stages of swallowing, in which food passes through the sensitive buccal-pharyngeal cavity. It would, however, be very unlikely to develop in the oesophagus itself or at the cardia, where the passage is entirely independent of voluntary action and the food under ordinary conditions is not felt, unless it is very cold, very hot or in large lumps.

Hysterical dysphagia is, however, rare. The majority of cases so diagnosed are examples of the Plummer-Vinson syndrome, and others are really suffering from myasthenia gravis. It develops in patients who have become nervous for various reasons when some trivial incident draws their attention to the voluntary but normally automatic act of swallowing. Much weight is lost. Recovery usually follows simple psychotherapy by explanation and persuasion.

DYSPHAGIA IN ORGANIC NERVOUS DISEASES

Dysphagia may occur in various organic nervous diseases as a result of paralysis of the muscles concerned in the first and second stages of swallowing. The oesophagus itself and the cardiac sphincter are never involved. In diphtheria the toxin not only invades the blood, but also ascends the nerves from the site of the lesion to the central nervous system, where it puts the cells of the corresponding nuclei out of action. The paralysis of the soft palate which results in regurgitation of food through the nose, and the rare pharyngeal paralysis which results in severe dysphagia occur therefore mainly in the common faucial diphtheria and far less often when the primary focus is in a wound, the conjunctiva or elsewhere. The paralysis is nuclear in origin and generally develops in the second week, in contrast with the more widespread paralysis caused by diphtheritic polyneuritis, which usually appears between the third and sixth weeks.

In motor neurone disease, dysphagia may occur if the vagal nucleus is involved in the last stages of the common form beginning in the muscles of the hands. It always occurs in progressive bulbar palsy, the form which begins in the bulbar nuclei. Though myasthenia gravis is a primary muscular disease, it gives rise to simple upper dysphagia in which the first as well as the second stage of swallowing is affected. In motor neurone disease the slowly progressive paralysis is unaffected by any treatment and there is no variation in the course of each day, so that once nasal feeding is begun it has to be continued until death, which is not likely to be long delayed. In myasthenia gravis the dysphagia increases in severity as the disease goes on, and considerable spontaneous improvement may occur from time to time so that a patient who has had to be fed temporarily by nasal tube may later be able to swallow quite well for weeks, months or years. Improvement in swallowing may be a direct result of the complete rest given to the muscles of deglutition by nasal feeding. The response to neostigmine is often dramatic. Neostigmine bromide 1 mg. can be given by mouth or neostigmine methylsulphate 1 mg. subcutaneously. Dysphagia is also a symptom of the acute bulbar paralysis which may follow vascular or inflammatory lesions involving the nucleus ambiguus.

In all forms of dysphagia due to organic nervous disease food of porridge consistency is most easily swallowed, as fluids require more rapid, and lumps more powerful, action than soft food.

PLUMMER VINSON SYNDROME

Synonym — Kelly Paterson Syndrome

Upper dysphagia with anaemia is the most frequent cause of difficulty in swallow

ing involving the junction of the pharynx and œsophagus. It occurs in about 15 per cent of cases of idiopathic hypochromic anæmia (see p 732), which is common in women, but very rare in men. The syndrome is the direct result of iron deficiency, which causes not only the anæmia, but also atrophy of the mucous membrane of the tongue and pharynx. The atrophy of the pharyngeal mucosa results in a loss of sensibility, so that the afferent side of the reflex upon which the second stage of swallowing depends is impaired. The orderly activity of the muscles involved in the complicated act is disorganised and swallowing becomes difficult or impossible. The pharyngo œsophageal sphincter is particularly involved, the normal relaxation which allows the passage of food from the pharynx into the œsophagus failing to take place. By œsophagoscopy an organic stricture may often be seen at the level of the crico-pharyngeal ring, sometimes with a thin crescent shaped web of mucosa obstructing the lumen.

Symptoms—The patient, generally an edentulous woman between 25 and 50 who has been in poor health for a long period owing to the presence of anæmia, gradually finds difficulty in initiating the act of swallowing, especially of solids. Sometimes, however, the dysphagia begins quite suddenly, and it may occur intermittently. Severe cases in which dysphagia is the main symptom are rare in comparison with those in which it is so slight that the patient does not mention it unless directly cross-questioned. The dysphagia is associated with atrophy and sometimes inflammation of the mucous membrane of the tongue and the pharynx. An atrophic condition also involves the lips, which may be thin and inelastic with cracks at the angles of the mouth. Achlorhydria is frequently, but not always, present, and the spleen is occasionally enlarged. The nails are often thin, brittle and spoon shaped (koilonychia).

A barium swallow using a thick emulsion may show filling defects with retention of some of the opaque material in the pyriform fossa and the œsophagoscope may demonstrate the atrophic, inelastic condition of the pharyngeal mucous membrane, which may contract and aggravate the dysphagia by adding a mechanical obstruction to the neuro-muscular disorder.

This atrophic condition of the mucous membrane predisposes to carcinoma. About 50 per cent of women with cancer of the mouth and a still larger proportion of those with cancer of the hypopharynx and upper end of the œsophagus give a history suggestive of the syndrome. The fact that the latter is almost confined to women probably explains why 80 per cent of cases of carcinoma of the post cricoid part of the pharynx, which always spreads to and obstructs the mouth of the œsophagus, occur in women, whereas at least 80 per cent of cases of cancer of the middle and lower end occur in men.

Treatment—The dysphagia usually responds well to treatment of the anæmia. Large doses of iron, and general treatment as outlined on p 733, are usually all that is required, but in some cases a large mercury bougie may be carefully introduced into the œsophagus if the condition requires. Sedatives and psychological treatment by encouragement and reassurances are also useful. The atrophic condition of the mucous membrane often responds to iron therapy with additional vitamins, even if there is no anæmia. In rare cases the syndrome occurs in association with true pernicious anæmia, in which case liver must be given in full dosage.

CARDIOSPASM ACHALASIA OF THE CARDIA

Ætiology—Achalasia of the cardia may begin at any age, but most commonly in adults, and males and females are equally affected. A sudden onset following nervous shock occurs in many cases, which suggests that the condition is at least partly due to psychological causes.

Pathology—The hypertrophy of the muscular coat of the œsophagus, which is

always present, indicates that violent efforts must have been made to overcome some obstruction. As no organic obstruction is ever found after death it was at first thought that spasm of the cardiac sphincter was present, and the condition was called *cardiac spasm*. As the symptoms may be present without intermission for many years before death, hypertrophy of the cardiac sphincter should result from the long-continued spasm. In very few necropsies, however, has there been any hypertrophy, and in several cases in which the cardiac sphincter, which is normally about 1 in. long and corresponds with the whole of the abdominal œsophagus, was exposed by operation, the muscle was found to be unusually thin. It was thought, therefore, that the obstruction was due to a failure of the cardia to open reflexly during swallowing, and Hurst suggested the name *achalasia* (*a*, not, *Xalasia*, relaxation) to indicate the absence of the normal relaxation, which should occur when each peristaltic wave reaches the cardia. Food stagnates in the œsophagus, which dilates as more and more collects in it; the distension of the œsophagus acts as a powerful stimulus to peristalsis, which is excessively violent and continues at intervals throughout the day. This is the cause of the hypertrophy.

Further evidence that the condition is due to achalasia and not to spasm is afforded by the fact that, although strong peristaltic waves are unable to overcome the obstruction, the weight of an indiarubber tube filled with mercury is sufficient to cause it to drop into the stomach, the actual passage through the cardiac sphincter being often inappreciable to the hand holding the mercury bougie, which can be withdrawn with equal ease. It is not gripped, as the finger is gripped when it enters or is withdrawn from a spasmodically contracted sphincter.

The exact cause of the achalasia is uncertain, though disease of the myenteric (Auerbach's) plexus has been suggested, psychological factors are certainly concerned.

The dilated œsophagus may be able to hold as much as 2 pints, and its circumference may exceed 6 in.

Symptoms—Achalasia of the cardia generally develops gradually, a slight attack lasting for a day or two, being followed by a period of freedom for a few days or even several weeks or months. Attacks then occur at gradually shorter intervals until finally the condition becomes permanent. The patient feels as if the food "sticks." He often recognises that the obstruction is beneath the lower end of the sternum, but sometimes the sensation is felt in the upper part or middle of the chest. Sometimes actual pain is produced, it is usually burning in character and is localised to the lower end of the sternum, but it may be indistinguishable from angina and may radiate to the neck, the ears or lower jaw. Salivation occurs in every case.

As a rule the patient voluntarily relieves his discomfort within a few minutes of finishing a meal by bringing up the greater part of what he has eaten mixed with saliva. He realises that this comes from his chest and not his abdomen, and, unlike true vomiting, it is not associated with nausea.

The weight of the column of food in the dilated œsophagus after a meal is sufficient to force a small proportion of the fluid present through the cardia as a very narrow stream, but as soon as the height of the column falls below a certain point, generally about 7 in., or the individual lies down, the pressure becomes insufficient and the flow ceases. Consequently, stagnating food mixed with mucus is always present in the œsophagus, and a considerable quantity can be removed from it even after a fast of 24 hours. No regurgitation occurs on lying down as the pharyngo-œsophageal sphincter is always, as in normal people, closed except during the act of swallowing.

The œsophagoscope shows that the entry to the cardiac sphincter, which is generally at the level of the diaphragm but may be within the thorax or within the abdomen is completely closed. The mucous membrane may be normal, but owing to the prolonged stasis of food it is often chronically inflamed, especially

in the lowest part, and there may be superficial erosions: hæmatemesis may occasionally result.

Even in the absence of treatment the general health may remain good in spite of the fact that weight is often rapidly lost. At a certain stage a condition of equilibrium develops. Though the diet has to be limited the patient loses no more weight, and though he is less strong than formerly, he may continue to remain in this condition for many years and attain old age.

Diagnosis.—The patient's description of his symptoms is generally so characteristic, that a diagnosis of obstruction in the region of the cardia can be made with a considerable degree of probability. It is next necessary to decide whether this is due to achalasia, cancer or spasm associated with œsophagitis or peptic ulcer. The comparatively early age of many patients, and, in cases in which an early diagnosis has not been made, the long duration of the illness point to achalasia rather than to growth. Pain is often late in carcinoma. The diagnosis is confirmed by radiography; in achalasia the shadow of the dilated œsophagus narrows abruptly and ends at the entry into the sphincter, either on a level with the diaphragm or a short distance above or below it. As each additional quantity of food is swallowed, a narrow and uniform channel is seen for a moment to join the œsophagus with the stomach before the sphincter closes again. In peptic ulcer of the lower end of the œsophagus the sphincter remains open, but a narrowing is seen just above as a result of spasm with or without cicatricial contraction, and the round crater of the ulcer may be recognisable. In carcinoma the lumen of the cardiac sphincter is replaced by an irregular channel which extends a varying distance up into the œsophagus, the unaffected part of which is never as dilated as in achalasia, and except in the later stages the opaque fluid continues to pass slowly through the narrow irregular channel into the stomach till the œsophagus is empty, whereas it is never empty in achalasia. If there remains any doubt, the diagnosis of achalasia may often be confirmed by inhaling octyl nitrite, which results in dilatation of the sphincter and evacuation of the œsophagus. (œsophagoscopy should be carried out both to confirm the diagnosis and to undertake treatment (*vide infra*).

Prognosis.—If the condition is recognised at the onset of symptoms, a permanent cure often results from treatment, but if treatment is instituted only after the œsophagus has become dilated, cure as distinct from mere relief of symptoms is less likely to be obtained. There is practically no spontaneous tendency to cure, but approximately half the patients treated early remain well after dilatation. In the absence of treatment death has occurred at an early stage in very acute cases; but more often the patient survives for a considerable period, even for 40 years. In rare cases a diverticulum may form in the lower end of the dilated œsophagus or cancerous degeneration of a papilloma developing on the chronically inflamed mucous membrane may occur. In long-standing cases respiratory complications may result from pressure by the enormously distended œsophagus, or from regurgitation of the œsophageal contents into the pharynx and aspiration into the lungs.

Treatment.—Nitrites are the only drugs which cause relaxation of the closed cardiac sphincter. Unfortunately their effect is evanescent, and in the case of amyl nitrite, the general symptoms produced are so unpleasant that it is rarely of use. Octyl nitrite is more satisfactory, having less smell and causing no side-effects other than some drying of the mouth and the bronchial secretions. It can be sniffed up the nose from a small metal inhaler and, as a rule, two or three sniffs at a time during and just after a meal are sufficient to cause relaxation of the cardia and the passage of the food into the stomach. The food should be soft and as far as possible of high calorific value, such things as vegetable soups thickened with sugar and cream, egg-flips, and malted milks being preferable to tea, meat broths or jellies: additional vitamins should be given, especially if there is much wasting. Many patients may be kept in good health and weight by these means alone, but dilatation often becomes

necessary and is usually very effective. The passing of mercury bougies as introduced by Hurst has been superseded by the use of a distensible bag, which can be gradually inflated with water. By this means the lower end of the œsophagus can be stretched and many of the circular fibres ruptured. The procedure can be controlled endoscopically and is often followed by lasting relief. If not, some form of open surgical operation should be advised. This is best done by simple surgical division of the circular fibres at the œsophageal opening (Heller's operation), comparable to a pyloroplasty. Various alternative and more elaborate operations which lead to permanent incompetence of the cardiac orifice are less satisfactory, since they lead later on in nearly every case to troublesome or serious œsophagitis. In severe cases œsophago-gastrostomy may have to be carried out. Either the abdominal or trans thoracic route may be employed.

Modern surgical treatment offers an excellent chance of cure, and should not be withheld too long if symptoms are at all severe. Even though the radiological findings after operation do not show great reduction in the dilated œsophagus, the symptomatic result may nevertheless be very good.

DIVERTICULA OF THE PHARYNX AND ŒSOPHAGUS

Ætiology and Pathology.—Diverticula may develop from the anterior wall of the middle third of the œsophagus, by the traction resulting from adhesions between inflamed glands near the bifurcation of the trachea and the wall of the œsophagus, these "traction diverticula" are generally less than an inch in depth and rarely give rise to symptoms.

A diverticulum, which has given rise to no symptoms, is occasionally discovered at the lower end of the œsophagus during routine radiographic examination, these are usually congenital in origin, but occasionally are found in association with achalasia of the cardia.

Pressure diverticula are rare, but of considerable clinical importance. They occur only in adults, especially elderly edentulous men who habitually swallow lumps of unchewed food. They develop at the muscular gap on the posterior wall of the pharynx between the upper and lower divisions of the inferior constrictor of the pharynx at the level of the cricoid cartilage. They are really diverticula of the pharynx and not of the œsophagus, though they are generally described as œsophageal. The lower division of the inferior constrictor of the pharynx (the crico-pharyngeus muscle) forms a sphincter surrounding the entrance to the œsophagus. It is closed at rest, but opens during each act of deglutition the moment the food reaches it. When as a result of neuro-muscular inco-ordination, it fails to open (achalasia) the food is forced against the weak spot on the posterior wall of the pharynx immediately above the sphincter. A pouch of mucous membrane may thus be formed. This becomes progressively larger towards one side, generally the left, owing to the accumulation of food in it, until it may finally measure as much as 5 in. in depth and be large enough to contain over a pint of fluid, in which case it may extend into the posterior mediastinum. Its wall is formed of mucous membrane and submucous tissue without any muscular covering.

Symptoms—Diverticula of the pharynx sooner or later cause progressive dysphagia, which may be preceded by irritation of the throat and increased secretion of mucus. The patient complains of obstruction in the neck when he swallows, and a small quantity of food is regurgitated at varying intervals after meals. As the size increases in size, the symptoms become more marked owing to obstruction of the œsophagus by the distended diverticulum, which finally forms a prolongation of the pharynx, the œsophagus opening as a transverse slit in its anterior wall. Increasing quantities of food are brought up, mixed with a large amount of mucus, and food

eaten several days before may be recognised. The patient becomes steadily more emaciated. Distension of the sac often causes pain, which is relieved when it is emptied. An irritable cough is often present, and dyspnoea may result from pressure on the trachea. A large diverticulum containing food may form a visible tumour in the neck, generally on the left side, which can be emptied by pressure, the food returning into the pharynx, but in most cases there is no palpable tumour.

The size, shape and exact position of the diverticulum can be recognised radiographically after a barium meal.

Treatment.—The only satisfactory treatment is excision. Whilst waiting for operation the patient should be fed through a catheter, which is introduced over a string swallowed when the sac is empty, if no fluids are taken for 5 or 6 hours the string always reaches the stomach.

ŒSOPHAGITIS

Two distinct forms of œsophagitis occur, both of which may be either acute or chronic. In one the irritants which cause it are either hæmatogenous or swallowed. In the other form, which, unlike the first, is often associated with ulceration, the essential factor is the presence of acid gastric juice in the œsophagus.

A SIMPLE ŒSOPHAGITIS

(a) *Acute*

Ætiology.—Acute simple œsophagitis is a rare complication of various acute infections and toxæmias, such as scarlet fever. It may also complicate cancer of the œsophagus and spread from acute pharyngitis. In 5 per cent of fatal cases of diphtheria the inflammation spreads from the fauces into the œsophagus, and in very rare cases the membrane extends as far as the cardia. The impaction of a foreign body in the œsophagus may cause local suppuration. Acute inflammation results from swallowing boiling water or corrosive poisons, taken by accident or in attempted suicide, owing to the obstruction to the passage of the œsophageal contents caused by the narrow cardiac sphincter the lower end is the part most affected, the upper extremity being next most seriously injured.

Symptoms.—In mild cases there may be no symptoms, but more or less dysphagia is generally present, in severe cases deglutition is so painful that the patient may be afraid to swallow his saliva or relieve his urgent thirst by drinking. There may also be constant pain beneath the sternum. Attempts to swallow often prove unsuccessful owing to reflex spasm, and the food is immediately rejected. Mucus is expectorated, together with blood and pus in severe cases.

Treatment.—In severe cases nothing should be given by mouth, but saline solution must be injected into the rectum or intravenously. Morphine is required for the pain. When the pain begins to subside a tablespoonful of olive oil followed by 5 oz of milk can be given every 3 hours. Solid food should not be given until swallowing no longer causes pain. Complete obstruction necessitating gastrostomy is likely to occur in severe cases following corrosive poisoning.

(b) *Chronic*

Ætiology.—Chronic œsophagitis results from the constant swallowing of irritants, the most important of which are strong alcoholic drinks, and from septic conditions of the teeth and nasopharynx. It is also a common sequel of the stasis of food in the dilated œsophagus in achalasia of the cardia (p 543).

Symptoms—As the condition is frequently associated with chronic pharyngitis and gastritis, it is generally impossible to isolate the symptoms of one of these from the others. The morning vomiting of alcoholics is mainly the result of œsophageal catarrh.

Treatment—The œsophagitis usually disappears when the sources of irritation are removed. The patient should become teetotal, and all septic foci in the mouth and pharynx should be treated.

B PEPTIC ŒSOPHAGITIS AND ULCER

(a) *Acute Peptic Œsophagitis and Œsophageal Ulcer*

Ætiology and Pathology—Acute peptic œsophagitis and acute œsophageal ulcer occur at all ages, the latter is one of the causes of fatal hæmatemesis and melæna in infants. It is always a sequel of severe vomiting in an enfeebled individual with low resistance. The acid gastric contents are retained in the œsophagus just above the closed cardiac sphincter, where their irritant action gives rise to inflammation. The lower end of the œsophagus being generally alone involved. In most cases the acute œsophagitis is associated with the presence of one or more acute ulcers just above the sphincter.

The majority of cases follow post operative vomiting. Less frequently they result from the vomiting caused by pyloric obstruction secondary to a chronic gastric or duodenal ulcer.

Symptoms—An important symptom of acute œsophageal ulcer is hæmatemesis. It may begin between 24 and 48 hours after an operation which has been followed by severe vomiting. Heartburn and occasionally a burning pain may be felt behind the lower end of the sternum, especially on swallowing. The symptoms rarely persist for more than 10 days after an operation, but in other cases they may continue for long periods, though it is uncertain whether a chronic ulcer ever develops from this condition. Death may occur from hæmorrhage or from perforation of an acute ulcer into the pleural cavity, sometimes without any warning symptoms.

Treatment—The patient should be kept in the erect position and given small milky and semi solid feeds every 3 hours. Five minutes after each feed he should drink a few ounces of water, and alkalis may be given freely for relief of pain.

(b) *Chronic Peptic Œsophagitis and Œsophageal Ulcer*

Ætiology—Simple chronic ulcer of the œsophagus was formerly regarded as little more than a pathological curiosity, but a recognition of its clinical features has in recent years shown that it is not uncommon. The incidence is greater among men than women, the majority occur between the ages of 50 and 70.

Pathology—Œsophageal ulcers have all the anatomical characteristics of chronic gastric and duodenal ulcers. In fatal cases heterotopic gastric mucous membrane has sometimes been found in the œsophagus, it probably secretes acid gastric juice which collects in the lower end of the œsophagus immediately above the closed sphincter, and in course of time an erosion and finally a chronic ulcer develops as result of peptic digestion of the very vulnerable stratified epithelium. In a large majority of cases, however, the ulcer is associated with a hiatus hernia (q.v.).

Symptoms—Discomfort or pain, often of a burning character and sometimes described as heartburn occurs under the lower third of the sternum whilst eating solid food, hot drinks or strong alcohol. The pain may also occur on leaning forward and shortly after lying down. It often radiates to the back and occasionally to the left shoulder or left side of the neck. At first the pain lasts for only a few minutes but later it is prolonged and the patient may become frightened to eat. The food

sometimes appears to stick at the lower end of the œsophagus before passing into the stomach. The spasm which causes the dysphagia sometimes leads to effortless regurgitation of sour material. The pain is relieved by alkalis and can generally be completely prevented by taking only fluid food. Progressive emaciation and anæmia are common in chronic cases. As with chronic gastric and duodenal ulcer, the symptoms at first occur for periods of varying duration with intervals of complete freedom.

Occult blood is present in the stools. Hæmatemesis, which may be severe but is rarely fatal, occurs in about 20 per cent. of cases and may be the earliest symptom. Perforation into the mediastinum, pericardium or peritoneum is rare, but it is a more common cause of death than hæmorrhage. In very chronic cases a fibrous stricture may develop and lead to more or less complete obstruction: much fibrosis and thickening of the œsophageal wall is found on microscopic examination.

The clinical picture may be confused by association with a gastric or duodenal ulcer. Excessive salivation is common. This may lead to aerophagy, which occasionally causes severe pain in the left hypochondrium owing to inability to expel the excess of gas from the stomach on account of œsophageal spasm (*œrogastrie bloquée*).

Radiographic examination during the swallowing of a barium emulsion generally shows no abnormality, though the emulsion may be held up by spasm at the lower end of the œsophagus. The œsophagus may be slightly dilated, but there is never anything approaching the characteristic mega-œsophagus caused by achalasia of the cardia. When a semi-solid opaque meal is swallowed, or if the opaque emulsion is swallowed whilst the patient is lying down, a characteristic picture is obtained. This consists of a narrowing caused by spasm near the lower end of the œsophagus; below this is a rounded shadow corresponding with the crater of the ulcer, and below this again is the cardiac sphincter, in which two or three longitudinal folds can often be recognised, passing to the stomach, which is often partially herniated into the chest.

It is advisable to confirm the diagnosis by œsophagoscopy, though occasionally the ulcer itself cannot be reached owing to the spasm just proximal to it. If there is any doubt about the nature of the ulcer, a fragment of its margin should be removed for microscopical examination. The ulcer is always associated with inflammation of the mucous membrane of the lower third of the œsophagus.

Diagnosis.—The diagnosis of peptic œsophageal ulcer must be made from a consideration of the symptoms, as the condition is generally missed in a routine radiological examination. The latter, however, serves to exclude cardiospasm and cancer of the œsophagus, which might be regarded as the cause of the dysphagia, though substernal pain and heartburn are rarely present in the former.

Ulcer of the œsophagus is clinically indistinguishable from peptic œsophagitis affecting the lower end of the œsophagus; the latter may be associated with spasm, but no actual ulcer can be recognised either with the radiogram or the œsophagoscope.

Treatment.—A patient with severe œsophageal ulcer should be given fluid feeds only and treated in the sitting position so as to lessen stagnation in the lower end of the œsophagus; he should drink a few ounces of water a quarter of an hour after each feed so as to wash its remains into the stomach. Maximal doses of atropine and a tablespoonful of olive oil should be given a quarter of an hour before each feed in order to overcome spasm. The treatment should be continued until not only all pain and dysphagia have disappeared, but also until the radiograms show no trace of a crater and the occult blood has disappeared from the stools. If the ulcer does not heal within a couple of months, or if, when first seen, much cicatricial narrowing with secondary stasis in the œsophagus is present, surgery should be advised without delay. A gastrostomy may be necessary, followed by an anastomosis between stomach and œsophagus, performed through a transthoracic approach, or a partial resection of the œsophagus may be possible. Cases of moderate stenosis may be treated by endoscopic dilatation.

ŒSOPHAGEAL HIATUS HERNIA

Synonyms—Diaphragmatic Hernia, Thoracic Stomach

In this condition part of the stomach is herniated into the thorax through the œsophageal opening in the diaphragm. In a few cases this is a congenital abnormality—short œsophagus—but in the majority it is acquired, and results from relaxation or trauma of the tissues at the diaphragmatic opening, with an increase in intra abdominal pressure due to such causes as pregnancy, obesity or continued coughing. Most œsophageal herniæ are of the sliding type, in which the stomach is drawn through the diaphragmatic opening, the cardiac sphincter is incompetent, and acid regurgitation and œsophagitis occurs. In others, a part of the fundus of the stomach herniates into the chest alongside the œsophagus—paraœsophageal hernia—and there is less chance of acid regurgitating into it. A congenitally short œsophagus and œsophageal inflammation such as follows the swallowing of caustics may draw the stomach upwards through contraction of scar tissue, and congenital absence of part or all of one side of the diaphragm may also occur.

An œsophageal hernia may be present intermittently and is usually found in middle aged women who are overweight. It may remain symptomless or give rise to belching fullness after meals and epigastric or substernal discomfort. If there is acid regurgitation into the œsophagus, a sensation of burning behind the sternum occurs, which may radiate to the back, arm, neck and ears. With a paraœsophageal hernia there is often a complaint of a lump in the throat, asthma and "wind round the heart".

Diagnosis—The diagnosis may be difficult to make, but the most important characteristic is the relationship of the symptoms to posture rather than to eating. Bending forward as in digging, or doing up a bootlace brings on the discomfort burning or pain, which may also occur when the patient lies down in bed. It is usually relieved by sitting up and by alkalis. It must be distinguished from the pain of angina pectoris, which is more related to exertion than position, and from the symptoms of peptic ulcer, gall bladder disease and nervous dyspepsia. In any case of suspected hiatus hernia a special radiological examination should be made in the particular position which causes the pain, when gastro œsophageal regurgitation of barium may be seen and the herniation demonstrated.

Treatment.—In treatment much may be done by relieving the patient's mind about the pain and the absence of heart disease, and by advice to avoid bending and to sleep propped up in bed. If there is œsophagitis a regime similar to that advised for peptic ulcer should be given and only if the symptoms are severe should surgery be considered. In this case, operation using the thoracic approach to reduce the hernia and fix the stomach in position may be successful or more extensive procedures if an œsophageal stricture is present. Anaemia sometimes arises from hiatus hernia in which case iron should be given in full dosage. Symptoms occurring in pregnancy usually improve after delivery, when the intra abdominal pressure has fallen.

NON-MALIGNANT STRICTURE

Ætiology—Stricture of the œsophagus is in rare cases congenital, the middle part of the œsophagus may be represented by a fibrous cord, or the lower part may open into the trachea or into one of the bronchi. It may also be a sequel of the acute œsophagitis resulting from caustic poisoning or the impaction of a foreign body and of the healing of a chronic peptic ulcer just above the cardiac sphincter. At œsophagoscopy concentric narrowing of the œsophagus may be seen, or irregular scarring with evidence of healed ulceration and peri œsophageal adhesions. Syphilitic strictures are very rare.

Treatment—Dilatation of the stricture causes bleeding and any persisting inflammation is increased by the trauma leading to still further fibrosis. If the stenosis is sufficient to cause dysphagia, surgical resection of the diseased portion of œsophagus is necessary, which may have to be preceded by gastrostomy. Various methods of restoring the continuity of the œsophagus have been devised.

CANCER OF THE ŒSOPHAGUS

Ætiology—Cancer of the œsophagus occurs with about one-third the frequency of cancer of the stomach. Over 70 per cent of all cases occur in men, but 80 per cent. of upper œsophageal growths occur in women (p. 543). Among 100 cases of cancer occurring in the alcohol trades (barmen, cellar-men, waiters and brewers) about 15 affect the œsophagus compared with 7 in men working in other trades, suggesting that the chronic œsophagitis caused by excessive indulgence in alcohol may be a predisposing cause.

Pathology.—Most growths of the œsophagus are epitheliomata. They are most common in the lower end and then at the level of the bifurcation of the trachea, these being the narrowest parts, the mucous membrane being consequently most subjected to friction by coarse food. Less frequently they occur at the upper end of the œsophagus, it is then impossible to say whether an epithelioma is a primary growth of the pharynx, from which it has spread into the œsophagus, or a primary growth of the œsophagus which has spread into the pharynx. Ulceration occurs at an early stage. Accumulation of food above the obstruction leads to progressive dilatation, and the efforts of the œsophageal musculature to overcome it results in hypertrophy, but the dilatation and hypertrophy are comparatively slight except in cancer of the lower end, as when the obstruction is higher up, vomiting occurs so quickly that very little food can accumulate.

Symptoms—Dysphagia is almost always present, and is the first symptom in a large majority of cases. Most frequently a patient in perfect health one day experiences a slight discomfort on swallowing, soon he notices that his food seems to stick for a moment before passing on into his stomach. The difficulty becomes slowly but steadily more marked, with rare intermissions lasting for a few meals or at most for a few days. The patient often manages to swallow his food by chewing more thoroughly, by taking smaller mouthfuls and by drinking after each mouthful. More and more effort is required, until after a period, which is generally between 1 to 4 months but may be as long as a year and a half, solid food ceases to pass at all and is regurgitated into the mouth a few seconds later. After an average of 8 months there is complete obstruction to the passage of fluids as well as solids. The patient generally localises the position of obstruction correctly, but he occasionally thinks that it is in the upper end when it is really in the lower third.

Pain is not an early symptom and occurs in only about 50 per cent. of cases, it is most frequently absent when the growth is in the lowest third of the œsophagus. It occasionally begins a few days before or simultaneously with the dysphagia, but more commonly it is not noticed until the latter has been present for 1 or 2 months. The pain may be present only during deglutition, disappearing as soon as the food passes the obstruction. It is situated at the level of the obstruction and often passes through to the back.

Regurgitation of food almost always occurs sooner or later. It generally begins between 1 and 2 months after the onset of symptoms and is rarely delayed as long as 6 months. When the growth is situated in the upper third of the œsophagus the food is violently ejected out of the mouth or even from the nose after a coughing effort. When the middle or lower third is involved, the food regurgitates without effort into the mouth, often immediately after meals. If the œsophagus is dilated,

food may be regurgitated any time up to 2 hours after being swallowed. The food is completely undigested and always contains mucous saliva, often in considerable quantity, as continuous salivation is common. Regurgitation of saliva alone occurs when the obstruction is sufficient to interfere with the swallowing of fluid. The regurgitation of the contents of the dilated œsophagus gives relief to any discomfort or pain which is present. The regurgitated material sometimes contains blood and pus, and in exceptional cases is very foul, occasionally several ounces and, in rare cases, a large quantity of blood is vomited.

Progressive emaciation occurs owing to the small amount of food which is taken and when obstruction is complete the loss of weight is very rapid. The appetite may remain good, and hunger may be very distressing in the early stages, but this becomes less marked as the disease progresses. Severe thirst with dryness of the mouth is sometimes present, and fetid breath is common when there is extensive ulceration. In the late stages small hard glands are often felt in the neck, especially just above the inner end of the clavicle and beneath the lower jaw.

The vagus or recurrent laryngeal nerves, especially of the left side, may be involved and one, or rarely, both vocal cords may consequently be paralysed. Pressure on the cervical sympathetic may cause contraction of the pupil with slight enophthalmos and narrowing of the palpebral fissure on the affected side. Compression of the trachea or the main bronchi by the tumour or by secondary glands may cause hoarseness, coughing and dyspnoea. Perforation into the trachea or a bronchus gives rise to a paroxysm of coughing and dyspnoea whenever food is swallowed, and death from broncho pneumonia or gangrene of the lung is likely to occur. Perforation into the pleural cavity may produce an empyema, but a serous pleural effusion may develop without perforation.

Diagnosis—In a large proportion of cases it is possible to make a definite diagnosis from the history and from the information obtained by radiography, which should always be used without delay in cases of dysphagia. Before giving the opaque meal the thorax should be examined from every direction in order to exclude an aneurysm, although in the very rare cases in which this causes dysphagia other more characteristic symptoms generally make the diagnosis clear. Occasionally a growth of the œsophagus or secondary glands throw a shadow in the radiogram, but this is rarely obvious until the symptoms have been present for a considerable time. With an opaque meal the radiograms show the position and length of any narrowing; of the lumen of the œsophagus, the degree of dilatation above the obstruction and the amount of obstruction, but the latter may be in part caused by spasm. In the earliest stages, when the lumen is not much reduced, the semi fluid opaque meal may pass down without revealing any abnormality. Some ordinary food which is known to cause pain or difficulty should then be swallowed with the opaque fluid, spasm is induced and the position and extent of the growth can be clearly recognised.

The diagnosis of a growth from achalasia of the cardia has already been considered (p. 545). The presence of hard glands in the neck makes the diagnosis cancer extremely probable. In those cases in which the history and the radiogram leave the diagnosis in doubt, and especially in early cases an examination should be made with the œsophagoscope, by means of which the nature of the obstruction can generally be recognised and a fragment removed for biopsy, though failure to detect malignant disease in the excised fragment does not exclude the possibility of cancer.

There may be considerable difficulty in diagnosing between an epithelioma of the lower end of the œsophagus, which spreads upwards, but very rarely downwards into the stomach, and a primary carcinoma of the fundus of the stomach, which almost invariably involves the cardiac orifice sooner or later. With the former the dysphagia is the first symptom, with the latter anorexia, pain after food, loss of weight and

strength, vomiting and increasing pallor may appear before the dysphagia, but this is not always the case, as dysphagia may be the only symptom. When the tumour is gastric in origin the radiographs show a filling defect, together with irregularity of the folds of mucous membrane and encroachment on the transparent arc which is normally formed by the gas in the fundus, and sooner or later a mass can be felt high up under the left costal margin.

Prognosis—Growths of the œsophagus are of high malignancy and tend to metastasise early, death usually occurs between $2\frac{1}{2}$ months and $2\frac{1}{2}$ years after the onset of symptoms, the most common period being between 6 and 12 months. It is most frequently due to broncho pneumonia, exhaustion from starvation, or the effects of metastases.

Treatment—The radical treatment of cancer of the œsophagus by excision of the growth has until recently rarely been successful. Improvements in the technique of thoracic surgery have however resulted in the successful removal of a steadily increasing number of growths in the middle and lower end of the œsophagus. Various forms of gut or skin tubes to unite pharynx and stomach outside the thorax have been adopted, mostly using a loop of jejunum as an artificial œsophagus. Œsophago-gastrostomy may be possible but in inoperable cases gastrostomy may be the only means of maintaining nutrition when obstruction is complete.

As the diagnosis of carcinoma of the œsophagus in the early stages is not difficult, the prospects of radical surgery may well improve in the future, but at present the mortality rate is high.

Radiotherapy may be given either by massive dosage of deep X-rays or by direct application of radium, but holds out less hope of cure than surgery. The most successful method has been by direct irradiation of the growth at open operation, so partly avoiding the damage to other tissues which adequate irradiation may otherwise cause. Unfortunately growths of the œsophagus spread locally and by lymphatics early and make radical excision or irradiation extremely difficult. The operative mortality of suitably selected cases lies between 20 and 30 per cent.

With modern surgery and the modern forms of radiotherapy, it is now rarely necessary to insert tubes, but if obstruction in the middle of the œsophagus cannot be overcome, a spiral metal tube should be introduced through an œsophagoscope, if necessary after preliminary dilatation of the stricture by bougies. Its lower end reaches beyond the growth, whilst the upper funnel shaped end rests on its proximal margin. The tube can be left *in situ* until the end, but it sometimes leads to so much dilatation that it passes through the obstruction and is expelled *per anum*.

So long as any obstruction is present the food should be semi fluid or fluid, and should be taken in small quantities at frequent intervals. As large a dose of atropine as possible, short of producing unpleasant symptoms, given half an hour before each feed and a dessertspoonful of olive oil just before, often help its passage through the stricture.

THOMAS HUNT

DISEASES OF THE STOMACH

INTRODUCTION

GASTRIC SECRETION

The healthy stomach secretes gastric juice continuously day and night in varying amounts under varying circumstances, the resting volume being normally about 10

to 15 ml. per hour. It is made up of hydrochloric acid secreted by the parietal (or oxyntic) cells, found in the body of the stomach, alkaline mucus secreted by the mucoid cells, and pepsin, secreted by the chief cells situated mainly at the pylorus. In addition to these specific secretions, the gastric juice contains water, neutral salts (mainly chlorides) and small amounts of urea, amines and ammonia. It is probable that these various constituents of the gastric juice may be independently affected by different stimuli so that it may vary considerably in composition from time to time, and is not uniformly the same under all conditions in the same individual. The parietal cells secrete, however, a relatively constant strength of almost pure hydrochloric acid which is constant in each individual—being approximately 0.154 to 0.2 normal concentration. The volume of juice secreted varies greatly under different circumstances, and the acidity and peptic activity also alter, both as regards the amounts actually secreted and through the effects of dilution with other gastric secretions, saliva, ingested food and the regurgitation of alkaline duodenal contents. In addition, the acidity may differ somewhat in different parts of the stomach, the cardiac end being more acid than the pyloric, especially at the beginning of digestion.

Variations in gastric secretion may also be constitutional, varying from individual to individual, so that different personalities and different physical builds may be associated with different types of gastric secretion. Constitutional variations in gastric secretion may sometimes be familial, and may undoubtedly play a part in the predisposition to certain types of gastric diseases or dysfunction (*vide infra*). At the same time it is important to emphasise that terms such as hypersecretion, hyperchlorhydria, hyperacidity and their opposites hypo- or achlorhydria do not themselves represent diseases but are merely names for secretory variations which are quite compatible with perfect health, good digestion and a normal expectation of life except for the possible development of certain diseases to which they may predispose. These secretory variations are often associated with characteristic temperaments and personalities—the hypersecretory for instance being often found in the ambitious, restless, energetic individual, and the normal or low secretory in the more phlegmatic, resigned and apathetic type.

In a hypersecretory stomach the resting secretion of juice is usually highly acid and of large volume whilst the mucus secretion is generally low, so that when this is associated with a rapidly emptying stomach the duodenum is likely to receive large amounts of acid juice, and the risk of duodenal erosions or ulcer developing is

of anæmia or nervous symptoms. The occurrence of pernicious anæmia and subacute combined degeneration of the cord in more than one member of the family is due to the familial occurrence of constitutional achylia gastrica and hypochlorhydria, which may depend upon a primary atrophy of the gastric mucosa. Moreover, achylia is often present without any abnormality of the blood or central nervous system, in relatives of patients with these diseases.

Regulation of gastric secretion.—The secretory cells of the stomach are influenced by both excitatory and inhibitory stimuli, which may be either nervous or chemical. The main nervous pathway is through the vagus, a psychic stimulation of secretion being set on foot via this nerve by the sight, smell or even thought of food. This psychic phase of secretion begins before food enters the stomach and is markedly affected by emotions, being greatly inhibited by feelings such as fear and sadness and accelerated by feelings such as anger, resentment and anxiety. Prolonged periods of emotional tension may thus lead to engorgement and hypersecretion in the stomach, both the continuous fasting secretion and the psychic secretion being affected. Surgical section of the vagus nerves has in consequence been recommended in treatment of gastric diseases (see p. 587).

Chemical stimuli.—The most powerful chemical stimulus to gastric secretion is histamine, which acts mainly upon the parietal cells, and much less powerfully, if at all, upon the pepsin and mucus secreting cells. Meat, meat extracts, peptones, liver extract, coffee and tea (containing caffeine), alcohol and most highly flavoured or irritant foods also act locally as excitors of the gastric secretion—some also if given parenterally. Besides this gastric phase of secretion regulated by chemical substances within the stomach, there are important regulating mechanisms acting through the intestine. The presence of acid in the duodenum, for example, produces an inhibitory effect as does the entrance of fats into the intestine, particularly upon the pepsin-secreting cells in the stomach. These effects are mainly produced through the bloodstream, and extracts of intestinal mucosa which have been in contact with fat have been shown to contain chemical agents which inhibit the gastric secretory response to a test-meal in the absence of any nervous mechanism. The name enterogastrone has been given to one such agent, which has been purified and studied extensively by Ivy, and others, and used in therapeutics with some success. The inhibitory effects of fats has also been made use of in treatment, by the giving of olive oil, milk, cream, etc., to reduce gastric secretion.

GASTRIC MOTILITY

Gastric movements have been studied both by radiography and by the use of balloons introduced into the stomach on the end of a Ryle's tube and connected to recording tambours on a revolving drum. By these methods gastric contractions are found to be of two types—short vigorous peristaltic contractions lasting about 30 seconds each, and smaller rhythmic contractions—tonus rhythm—occurring (during rest) from 1 to 3 times a minute. These movements mix up the gastric contents, and intermittently carry small amounts through the pylorus, which normally only opens for momentary periods at a time. Both types of gastric movements may be markedly increased by emotions such as resentment, and inhibited by others such as fear. They are also inhibited for a time by the ingestion of cold water and by fatty foods, and accelerated by the intake of proteins, broths and chemical irritants. Both types of gastric contraction may be increased during hunger, whilst tonus rhythm is lessened when the stomach is full. The emptying time of the stomach varies widely in different individuals, depending partly upon constitution and partly upon the above factors. In general each individual has throughout life a constant type of gastric emptying, either slower or faster, the average normal time lying between $1\frac{1}{2}$ and $4\frac{1}{2}$ hours. Emptying is slowest with dry solid mixed meals containing fat, and is quickest with fluid meals containing sugar but no fats.

GASTRIC SENSATION

If the abdominal wall is properly anaesthetised no pain is felt when the stomach is cut, pinched or cauterised. Acute mucosal ulcers are also quite painless unless they perforate the peritoneum and carcinomatous infiltration of the stomach may occur with practically no abnormal gastric sensation at all.

At the same time severe pain may undoubtedly arise from the walls of the stomach and is carried centrally by special pain nerves which may be stimulated either by tension or by chemical agents. The pain of peptic ulcer for instance is related both to increased muscular activity and spasm and to the acid contents of the stomach as shown both clinically and by many carefully controlled experiments. The threshold of pain both to muscular spasm and to acid stimulation, probably varies considerably in different individuals and in the same individual at different times. Feelings of gastric distension are related to the degree of tone with which the stomach holds its contents as well as to the actual volume of the contents themselves, in pyloric obstruction, for example, with extreme gastric distension tone and peristalsis may both be lost, pain be absent, and the sensation of stomach fullness directly related to the volume of the contents. On the other hand even a small meal in a nervous subject may cause a great feeling of fullness if the gastric tone fails to relax adequately to hold the food ingested. Many feelings such as appetite, hunger, nausea are excited centrally rather than locally, even though changes in gastric motility, vascularity and secretion occur with them, hunger does not necessarily result from an empty stomach.

FUNCTIONS OF THE STOMACH

1 *Digestion*—Foods are softened and mixed in the stomach whilst the pepsin of the gastric juice converts proteins to peptones in the presence of free hydrochloric acid. Its activity rapidly falls when the amount of free acid present sinks below 0.03 per cent until it finally ceases in complete achlorhydria. In spite of this digestion of proteins remains almost unimpaired in achlorhydria as the trypsin of the pancreatic juice is capable by itself of digesting all the proteins consumed in ordinary meals. An increase in the free hydrochloric acid above the average normal does not lead to any increase in peptic activity. Sugars and starches are little affected during gastric digestion whilst there is practically no absorption of foods or fluids other than alcohol and water. The gastric enzyme rennin converts the insoluble caseinogen of milk to the soluble casein.

2 *Protection of the small intestine from injury*—An important function of the stomach is to protect the small intestine from thermal, chemical and mechanical irritants. Very hot and very cold food and drink are brought to the body temperature, the gastric juice dilutes chemical irritants such as alcohol and softens hard particles and the churning movements in the prepyloric region break up lumps of insufficiently chewed food. At the same time the stomach attempts to protect its own mucous membrane from damage by secreting mucus in response to stimulation by chemical and mechanical irritants.

3 *The antiseptic acid barrier of the stomach*—The free hydrochloric acid of the gastric juice is a very efficient germicide and rapidly destroys streptococci swallowed from the mouth, throat and nose, as well as many organisms present in contaminated food and drink. It also helps to keep the reaction of the small intestine at a level which prevents its invasion by *Bact. coli* from the lower ileum and colon.

4 *Influence on the blood and spinal cord*—The gastric juice contains the 'intrinsic factor' of Castle, which acts on the 'extrinsic factor', which is present in protein

food, thereby facilitating its absorption. The intrinsic factor is produced by the glands of the body of the stomach.

The presence of free hydrochloric acid helps the conversion of the iron contained in food into a form in which it is easily absorbed, so as to become available for the production of hæmoglobin.

CAUSES OF GASTRIC DISORDERS

A ORGANIC

(i) *Mechanical, chemical and thermal irritants*—The mouth acts as the first line of defence in protecting the alimentary tract from damage by swallowed irritants. Food and drink are brought to the body temperature, chemical irritants are diluted, lumps of food are broken up by chewing and are intimately mixed with saliva, which softens hard particles and coats insoluble ones with mucus. Many people, however, bolt their food before it has been thoroughly masticated, and others have insufficient teeth and inadequate dentures, with the result that the stomach is daily subjected to mechanical, chemical and thermal irritants. It is also often damaged by excessive indulgence in alcohol, especially whilst fasting, or by strong tea and coffee, mustard, pepper, curry, pickles, raw or insufficiently cooked coarse vegetables, or tough meat. The stomach is frequently irritated, especially when empty, by the unconscious swallowing of the 'juice' of tobacco smoked in excess. Many people injure their gastric mucous membrane by taking drugs often quite needlessly, for supposed constipation, rheumatism and other self-diagnosed complaints, quite apart from those used in the treatment of definite chronic maladies—such are aspirin, bromides, iodides, digitalis, mercury, creosote and quinine. The contents of the duodenum act as irritants when introduced into the stomach, gastritis is consequently a frequent sequel of gastro-jejunostomy and partial gastrectomy.

(ii) *Infection*—Infected material is constantly swallowed by people with pyorrhœa alveolaris, infected tonsils, chronic pharyngitis and sinusitis, and by children with adenoids, also by those suffering from chronic cough as in bronchiectasis or pulmonary tuberculosis. In achlorhydria the antiseptic acid barrier of the stomach is lost, but when gastric juice is secreted in normal or excessive quantities, and even when it is deficient (in hypochlorhydria) such swallowed bacteria, with the exception of the tubercle bacillus are rapidly destroyed. Tubercle bacilli, on the other hand, are completely resistant to gastric acid.

(iii) *Hæmatogenous irritants*—Many acute infections may be accompanied by acute gastritis, which is often followed by chronic gastritis. The gastritis is due mainly to the direct action of bacterial toxins conveyed in the blood to the gastric mucous membrane, which perhaps makes an attempt to excrete them. Possibly the toxins produced in the body tissues themselves in acute infections may be in part responsible, just as the toxins of uræmia and substances produced in the skin in extensive burns may cause gastro-duodenitis and acute ulcers. The abdominal symptoms in gastric influenza are the result of acute gastritis, and acute ulcers and erosions are common in the stomach and duodenum in fatal cases of a great variety of infections.

Both the degree and the duration of these psychological factors influence the gastric changes. During periods of emotional conflict with anxiety, hostility and resentment, the gastric mucous membrane becomes red, engorged and turgid, and the folds become thicker and succulent so that a picture exactly resembling that formerly described as hypertrophic gastritis is produced. During this hyperæmic period the tissues of the stomach seem to become more sensitive to pain, and symptoms of indigestion may readily be aroused. Similarly, at this time the mucosa is more vulnerable to injury so that small erosions and bleeding may be produced. Such findings clearly demonstrate how easily nervous dyspepsia may arise through worry, anger, resentment and similar feelings, and how secondary organic changes, particularly ulcer, may follow from the same causes. Anxiety is a frequent cause of recurrence of peptic ulcer, and of the sudden increased activity of ulceration which may result in hæmorrhage or perforation. In the opposite direction feelings of well-being, contentment, joy, happiness, etc., are favourable to normal gastric digestion, whilst fear or depression, which involve feelings of withdrawal or defence rather than aggression, are associated with pallor of the gastric mucosa and inhibition of acid secretion and contractions.

Exhaustion from physical or mental overwork, insufficient sleep, malnutrition or from the toxæmia of chronic infections such as phthisis, and acute infections such as influenza has a depressing effect on bodily functions as a whole and may increase any liability to gastric symptoms which an individual may have. At the same time the stomach preserves its normal activity remarkably efficiently in many serious organic diseases and gastric studies of chronic invalids have shown that most of them are in fact able to digest a normal diet as well as healthy people, provided their psychological state and appetite are good. The sensation of pain from any part of the body, or any strong feeling of disgust or distaste may violently affect gastric motility so as to cause either temporary inhibition or even antiperistalsis and vomiting. The vomiting of coronary infarction, renal colic and other painful conditions belong to this group.

C REFLEX

Disorders of other abdominal organs may give rise to reflex gastric symptoms. Thus chronic cholecystitis, recurrent subacute appendicitis and diseases of the colon and urinary tract may all be associated with indigestion, and pyloric spasm in particular is apt to occur in these conditions.

Reflex stimuli from heart, pleura and other organs in the body may also set up gastric symptoms, as may reflexes from eyes or labyrinth as in Meniere's disease.

EXAMINATION OF THE STOMACH

1 CLINICAL

(a) *Size, shape and position*—Inspection of the abdomen may reveal the outline of the stomach in thin patients, especially if pyloric obstruction has led to excessive peristalsis. By palpation under similar circumstances the lower border of the stomach can sometimes be felt. Palpation may also reveal the presence of a tumour, the size, shape, position and mobility of which should be estimated. Percussion may give some idea as to the quantity of gas in the stomach, but it cannot help in the determination of its size, shape or position. Auscultatory percussion and friction have been shown by means of radiograms to be quite valueless for examining the stomach.

(b) *Tone*—Gastric splashing can be obtained in an individual with relaxed abdominal muscles and a stomach with normal tone, and gives little information as to the presence of deficient tone. Owing to the adaptation of the normal stomach to the

volume of its contents the upper level of these contents remains constant whether the volume is 4 oz or 40 oz, when the stomach is hypotonic this adaptation is less complete and the greater curvature tends to become more dependent with a greater air bubble and an increased area of gastric resonance on percussion at the cardiac end

(c) *Peristalsis*—In thin women normal peristalsis is occasionally visible, but in the majority of cases the presence of visible peristalsis indicates organic pyloric obstruction. The patient should be examined with a strong side-light soon after a meal or drinking half a pint of fluid. In doubtful cases peristalsis can be rendered more obvious by massage.

(d) *Rate of evacuation*—If gastric splashing can be produced by palpation over the stomach at a time when it should be empty—i.e. more than a few hours after the last food or fluid has been taken, gastric stasis is probably present but there are so many fallacies that this finding is of little diagnostic value.

2 RADIOLOGICAL

Plain radiography and screening of the stomach enables the upper level and amounts of its contents and the size of the air bubble in the cardia to be determined. For any complete study, however, a barium meal is required, and for this the patient should have at least 8 hours preliminary fasting. A small amount of barium emulsion is then swallowed and the gastric rugæ can first be outlined by palpation under screen control. When more of the opaque meal is drunk, the size, shape and movements of the stomach can be seen on the screen and radiographs taken. The patient should be photographed in the standing and prone positions, and also when bending well forward, in order to demonstrate any gastric herniation through or alongside the œsophageal opening. The shape and position of the stomach varies greatly and the greater curvature may lie vertically or almost completely transversely. The barium falls rapidly to the bottom of the body of the stomach, which may normally reach down as low as the pelvis. Peristaltic waves can be observed or any persistent spasm or incisure. A niche or constant crater may be seen indicating an ulcer or its irregular outline may suggest a carcinoma. A filling defect in the barium shadow which remains unchanged during the examination point to a growth, as do rigid unchanging rugæ or a tube like fixity of the barium outline. Normally the stomach is empty of barium in 1 to 4 hours, the average time being $2\frac{1}{2}$ hours. In cases of pyloric obstruction of whatever type, there is still barium present at 6, 8, 12 or more hours, and in some conditions such as migraine or states of fear and anxiety, nervous inhibition of peristalsis may cause much delayed gastric emptying time.

The value of radiological investigation in gastric and duodenal diagnosis depends greatly upon skilled screening by an expert radiologist, who is able to detect areas of tenderness, deformity or rigidity which may not be shown in the radiogram.

3 BIOCHEMICAL

The Ewald Carbohydrate Fractional Test-Meal provides a simple method of investigating certain gastric functions, and providing its limitations are appreciated, some useful information can be obtained. The test is performed by passing a Ryle's tube into the stomach of a patient who has been fasting since the previous evening. The total gastric contents are aspirated and measured, after which a meal consisting of either 1 pint of thin oatmeal gruel, or 2 slices of toast and a cup of weak tea is taken. Thereafter 10 ml of gastric contents are aspirated every quarter of an hour for 3 hours, or until no further samples can be obtained. The total and free acidity of each sample is determined, using Topfer's reagent and phenolphthalein as indicators, and they are also examined for the presence of starch and hile. Electrometric estima-

tion of the hydrogen-ion concentration of the samples allows the acidity of the unfiltered aspirate to be accurately determined: a pH of 3.5 is taken as the arbitrary level, above which free acid is assumed not to be present in any sample. If no free acid is found in any sample the test is repeated on the following morning, this time using 50 ml. of a 7 per cent. solution of alcohol instead of the carbohydrate meal, and giving a subcutaneous injection of either 0.5 mg. of histamine or 7 units of insulin 1 hour after the alcohol is drunk. If free acid still fails to appear in any of the samples, an achlorhydria is assumed to be present, although a high proportion of subjects who exhibit an histamine-fast achlorhydria to the test-meal, will show secretion of free acid in one or more samples if a 24-hour titration is undertaken.

The normal amount of resting juice found in man is subject to much variation, but if the fluid exceeds 40 ml. in volume and contains food residues, some degree of pyloric obstruction is probably present. Gross contamination of the resting fluid with blood may be due to gastric carcinoma or ulceration, but can also be due to epistaxis, oesophageal varices, acute gastric erosions or a friable hypertrophic gastric mucous membrane.

In gastric ulceration the amount of free acid found does not vary from normal, but in duodenal ulceration a high resting juice acidity is often found, and that of the remaining samples is usually raised. These findings are, however, often demonstrated in normal subjects with no clinical or radiological evidence of peptic ulceration.

Hypochlorhydria is often associated with microcytic anaemia, lenteric diarrhoea and post-prandial epigastric discomfort, but the symptoms are usually relieved by iron, and unrelieved by giving hydrochloric acid by mouth. Most patients with a gastric carcinoma show an achlorhydria at some stage during their illness, but the fact has little value in diagnosis. Almost all cases of pernicious anaemia have a histamine-fast achlorhydria.

A rough estimation of the emptying time of the stomach can be arrived at by testing the samples for starch, which should not be present after 2½ hours.

In 24-hour studies of gastric acidity it has been shown that most cases of duodenal ulceration secrete a large volume of highly acid juice all through the night, whereas normal subjects and patients with gastric ulcers only secrete intermittently during the night, and the juice is of low acidity.

Attempts to detect the presence of gastric carcinoma by microscopic examination of cellular fragments withdrawn with the gastric juice at a test-meal have not yet proved of consistent value in diagnosis.

4. GASTROSCOPIC

Gastroscopic examination of the stomach may provide useful information in certain cases. The procedure requires considerable experience both in the passing of the instrument and in interpreting results. There is a minimal risk of injuring the patient and the mortality risk is less than 0.1 per cent. The pharynx is first thoroughly anaesthetised and after passing the instrument most of the stomach may be visualised except the cardiac antrum, and the lesser curvature of the pyloric vestibule. In very anxious or elderly patients a general anaesthetic may be employed. The main value of gastroscopy lies in the demonstration of a gastric ulcer which has not been recognised by radiography and in a very few cases also of early carcinomata. In patients, therefore, who have gastric symptoms with negative clinical and radiological findings gastroscopy is of special value even if only in ruling out organic disease. It may be used to control the healing of a gastric ulcer, and indeed affords the only really certain evidence of complete healing, since both symptoms and radiographic examination may suggest that this has occurred though in fact an ulcer is still actively present.

Gastroscopy is helpful in the recognition of different forms of gastritis and of

erosions and acute or subacute ulcers, but the interpretation of the findings is not easy. It may be of value after hæmatemesis in excluding ulcer or demonstrating a hypertrophic gastric mucosa, and in diagnosing the cause of post-operative symptoms when radiology has failed to show anything abnormal.

It is possible by a special technique to remove small fragments of gastric mucosa at gastroscopy for biopsy and valuable evidence has been obtained in this way. Careful correlation, however, of gastroscopic findings with symptoms, biopsy and post-mortem examinations have shown that some of the appearances which were regarded as the result of acute or chronic gastritis were in fact only due to temporary changes in the mucosa induced by fear of the examination or other causes. Thus, the congested or reddened state of the mucosa, due to anger or frustration, was thought to be due to hypertrophic gastritis, whilst the palmar often seen in states of disgust or fear was thought to indicate an atrophic gastritis.

FUNCTIONAL DISORDERS OF THE STOMACH

VOMITING

Ætiology.—(1) **CENTRAL VOMITING**—(a) Many organic nervous diseases, such as cerebral tumour and meningitis, are accompanied by vomiting, which may also occur in compression caused by injury. This is generally due to increased intracranial pressure, and in cerebral tumour relief of such pressure often leads to cessation of vomiting. A mid-cerebellar tumour may give rise to vomiting as a result of direct pressure on the vomiting centre on the floor of the fourth ventricle long before other symptoms develop.

The vomiting of migraine is also of central origin. The cyclical vomiting of children is generally associated with a family history of migraine, and is often followed by true migraine in adult life. Such attacks may often rapidly lead to ketonuria and may, therefore, be wrongly regarded as caused by "acidosis". Though glucose may help in the prevention of such attacks, their true biochemical nature is not understood.

(b) Various emotions, particularly those of disgust or fear, may result in vomiting, especially in neurotic individuals. It may occur as a result of incidents which subconsciously revive the memory of an emotion which on some particular occasion caused vomiting. Thus, a woman who on one occasion vomited as a result of terror in a railway carriage, subsequently vomited whenever she travelled in a train, and after a time in any vehicle, and even in closed places, such as a church, from which she could not readily escape. The vomiting was associated with vague feelings of fear, but not consciously with the incident which was the primary cause.

(c) Hysterical vomiting represents a physical defence against some intolerable situation and usually occurs during or immediately after meals. It is effortless and generally unaccompanied by nausea, so that a patient may vomit meat and vegetables and immediately afterwards be ready to eat a sweet which he retains without difficulty. The stomach is, as a rule, only partially emptied, so that nutrition is preserved, but in rare cases nothing is retained, and severe emaciation, together with the changes in the urine which follow starvation and have erroneously been ascribed to toxæmia, result. The diet has little or no effect, vomiting being as frequent with milk alone as with a full diet.

(d) **Habit vomiting**. Vomiting is only rarely under the control of the will, but a person who has vomited a number of times may suggest to himself that certain circumstances will invariably cause him to vomit again. Similarly the habit of vomiting may persist after organic causes, such as whooping-cough.

(2) **REFLEX VOMITING**.—Painful stimulation of any afferent nerves, but particularly those of abdominal viscera, such as occurs in gastric ulcer, biliary and renal

colic, Dietl's crises and appendicitis, often causes reflex vomiting. Tickling the fauces is an easy means of inducing vomiting.

Sea sickness and air-sickness are caused by a reflex arising from excessive stimulation of the semi circular canals. The vomiting in diseases of the ear in which the semi circular canals are involved as in Meniere's syndrome, is of similar origin. The vomiting of early pregnancy is probably reflex, when persistent it is almost always hysterical, though other factors may also be concerned. This condition must be distinguished from the vomiting which begins in the later stages of pregnancy and is a symptom of pregnancy toxæmia (pre-eclampsia).

(3) **TOXIC VOMITING**—Substances produced in the body, as in uræmia hyperthyroidism and cirrhosis of the liver, may irritate the vomiting centre. In uræmia the action is partly reflex owing to the excretion into the stomach of toxins which should be excreted by the kidneys, and partly a result of increased intracranial pressure. Toxins formed in acute infections such as scarlet fever, pneumonia, hepatitis and influenza excite vomiting by their irritant action on the gastric mucous membrane and on the vomiting centre. Toxic vomiting differs from central vomiting and some cases of reflex vomiting, in being almost invariably preceded by nausea. It is a frequent symptom in active pulmonary tuberculosis (see, p 1023).

(4) **LOCAL GASTRIC IRRITATION**—Vomiting occurs when the gastric mucous membrane is irritated by decomposing or contaminated food, and by various inorganic and organic poisons. Thus, strong alcoholic drinks, or the consumption of foods to which an individual is sensitive such as shell fish (gastro intestinal allergy) may cause vomiting. Over-distension with food, especially if it occurs rapidly, as when a big meal is bolted, or if it continues for an abnormally long period as a result of pyloric obstruction, has the same effect. In all these cases more or less relief to the local symptoms follows the vomiting. Many drugs, particularly expectorants given medicinally in normal dosage may cause vomiting in sensitive individuals (idiosyncrasy) or in non sensitive patients if the dosage is high. Morphine is particularly liable to do so, as is quinine, whilst the vomiting caused by digitalis over dosage is especially important. Emetics, such as strong salt water, and copper and zinc sulphate act directly upon the stomach, but others such as apomorphine cause vomiting by direct stimulation of the vomiting centre. The former are, of course only effective when swallowed, whilst some such as tartar emetic, ipecacuanha and general anæsthetics act both locally and centrally. In the case of apomorphine the action may be rapid and violent and associated with considerable depression of the vasomotor and respiratory centres, and it must be used with caution.

(5) **OBSTRUCTIVE VOMITING**—The projectile vomiting of pyloric stenosis and that due to intestinal obstruction are described under their respective organic causes (see pp 594 and 651).

Treatment—The proper treatment of vomiting is to remove the cause. When it is the result of direct irritation of the stomach, complete evacuation gives relief. This can often be effected by tickling the pharynx or drinking a large quantity of warm water containing sodium bicarbonate. When these methods fail a stomach tube may be used. Sea-sickness and air sickness can often be prevented by taking gr 2½ each of phenacetin and soluble barbitone half an hour before and again shortly after starting on the journey, or gr 1½ of hyoscine if the vomiting is severe. The antihistamine drugs are also effective in sea sickness, and in some other conditions such as the vomiting of pregnancy.

REGURGITATION, HEARTBURN AND WATERBRASH

REGURGITATION—Regurgitation of unaltered food, mixed with more or less saliva, occurs with pharyngeal diverticula, and in œsophageal obstruction resulting from

achalasia of the cardia, and simple and malignant stricture. Regurgitation of small quantities of partially digested food into the pharynx and less often into the mouth, without effort and without nausea, occurs in various forms of dyspepsia, its acidity produces a scalding sensation in the pharynx. Regurgitation is frequently associated with flatulence due to air swallowing, the unsuccessful efforts to bring up wind when no excess is present in the stomach, resulting in regurgitation of some of its fluid contents. The regurgitation may later give place to vomiting, both the regurgitation and vomiting being to a great extent under voluntary control.

HEARTBURN—When the indigestion which gives rise to regurgitation is a result of some swallowed irritant such as excess of condiments, alcohol, tobacco or drugs, the gastritis, which is the cause of the indigestion, is likely to be associated with œsophagitis. Apart from this, frequent regurgitation of acid food through the œsophagus leads to œsophagitis. In whichever way the œsophagitis is caused, the œsophageal mucous membrane, which is normally insensitive to dilute hydrochloric acid, becomes sensitive, so that the gastric contents produce a sensation of burning behind the sternum when regurgitation occurs. This burning sensation is known as heartburn, and may occur with or without regurgitation into the pharynx and mouth, it is not closely related to the degree of gastric acidity, and may in fact occur in cases of gastric carcinoma with achlorhydria. It is particularly frequent in cases of hiatus hernia (*q v*).

WATERBRASH—Waterbrash may occur in any of the conditions which give rise to pyalism (*p 530*), but most commonly with duodenal ulcer. At a certain interval after a meal, which varies in different cases, but is fairly constant for each individual, an uncomfortable sensation of constriction, which may amount to severe pain, is felt deeply beneath the lower end of the sternum. This is accompanied by profuse salivation, and even sometimes by pain in the jaws from the rapid swelling of the parotid glands. Relief occurs on bringing up a few mouthfuls of clear fluid, which is generally described by the patient as being like water, though it sometimes contains a good deal of mucus. The fluid rises into the mouth with little or no effort and without nausea. It is sometimes so profuse that the patient may have to keep his mouth open to let the fluid pour out. It comes from the mouth and œsophagus and not from the stomach, as even when the previous meal was large and finished less than an hour before, no food is present in the regurgitated material, which is alkaline in reaction and has all the characters of pure saliva. When the flow of saliva is excessive, it runs down the œsophagus without the patient's knowledge and without the aid of actual swallowing, the cardiac sphincter being closed, the fluid collects in the lower end of the œsophagus.

The morning vomiting of alcoholic individuals is the result of a similar process, though it is accompanied by more violent vomiting efforts. In this case the fluid consists of saliva with a considerable proportion of pharyngeal and œsophageal mucus, secreted as a result of chronic pharyngitis and œsophagitis.

Treatment—No special treatment is required for regurgitation, heartburn and waterbrash beyond that of the primary condition. The discomfort caused by regurgitation and heartburn may often be overcome by drinking water or sodium bicarbonate solution, or by chewing and then swallowing an alkaline tablet.

ANOREXIA

Anorexia, or loss of appetite, occurs in a small proportion of cases of chronic gastritis and in the majority of cancer of the stomach, in which it may be the first symptom. It does not occur in uncomplicated gastric or duodenal ulcer. It is common in toxic conditions, such as acute fevers and tuberculosis, and is often present when for any reason the tongue is dry or furred. It is frequently due to psychological causes, in particular, anxiety and states of depression.

ANOREXIA NERVOSA

Ætiology.—Anorexia nervosa occurs in adolescents and young adults of both sexes, but much more commonly in females than males. There may be no family history of psychoneuroses or psychoses. The anorexia is in most cases at first the visceral expression of some emotional disturbance, often an unhappy love affair. Sometimes the diet is voluntarily reduced with the object of overcoming a real or imaginary tendency to get fat, or on account of some fanciful ideas concerning the effect of food in stimulating sexual activity. Whatever the origin of the condition may be, the restriction of food results in the gradual disappearance of the appetite until the patient loses all desire for food. After the anorexia has continued for some time its origin, which is rarely recognised by the patient without explanation recedes into the background, and it often remains after the psychological difficulties which gave rise to it have disappeared, but recovery usually follows psychotherapy without additional treatment of any kind.

Diagnosis.—Anorexia nervosa should not be confused with Simmonds's disease (see p. 487), which is a much less common condition, caused by degeneration of the pituitary gland, generally following childbirth with excessive hæmorrhage and post partum necrosis of the gland. This condition is uninfluenced by psychotherapy and is not necessarily associated with either anorexia or emaciation, but invariably with severe asthenia, loss of axillary and pubic hair, and frequently with premature senility, atrophy of the breasts and low metabolic rate.

In cases of gastric carcinoma the anorexia is particularly felt towards meat, whilst in simple loss of appetite due to anxiety it varies greatly with environment. Anorexia is a very constant symptom at the onset of infective hepatitis whilst in depressive psychoses it is a part of the general apathy and loss of interest in many things, including food and drink.

Symptoms.—The patient shows a complete loss of interest in every kind of food, and as even small quantities have to be forced down, they give rise to a sense of complete repletion distension and sometimes nausea. She may learn to vomit at will and as she realises that she can overcome her discomfort by this means, it may occur after every meal. The small intake of food leads to increasingly severe constipation and the aperients used for its treatment increase the abdominal discomfort.

The patient rapidly loses weight and in time becomes extremely emaciated, almost all the subcutaneous fat disappearing. At first physical and mental activity are unabated, the restless energy and absence of fatigue being in striking contrast with the wasted appearance of the patient, but in the later stages the patient becomes weak and lethargic, and finally may be in bed unable to move a limb or raise her head. In girls amenorrhœa is a constant symptom, it develops at an early stage and may persist for months after recovery is complete in all other respects. It is probably of psychical origin and not a result of malnutrition as it develops at an early stage and may persist long after the patient has returned to a normal diet. An abnormal growth of downy hair is a common symptom, this is a direct result of malnutrition as it is often observed in times of famine. Symptoms of vitamin deficiency only rarely develop even in cases of extreme malnutrition.

The pulse and temperature are normal. Radiographs show no abnormality in the alimentary tract, the constipation being due solely to the insufficient quantity of food residue, gastric secretion is unaffected. The extremities and the nose and ears are cold and blue, the skin dry and scaly. The urine is normal.

If proper treatment is not instituted death may result from inanition, extreme atrophy without any organic visceral lesion being found post mortem.

Treatment.—Except in the earliest stages it is essential to remove the patient from her home surroundings and to allow only infrequent visits from her relations.

The nature of the symptoms is explained to her, and she is made to understand that she can recover and return to her home and to a normally active life only when, as a result of eating a proper quantity of ordinary food, her weight and strength have returned, and that though this may entail some discomfort at first, her appetite is certain to return when more food is taken. It is essential to be present during the first meal after treatment is begun, and to be prepared to spend a very long time arguing over every mouthful until the meal is at last finished. As resistance almost invariably breaks down under these conditions, the task of supervising subsequent meals can be left to a good nurse, who must at first never leave the patient, as otherwise food is likely to be hidden or thrown away. The patient should from the first day of treatment be given a full diet without restrictions of any kind, and should be induced to eat everything she is given, and with tact, explanation and persuasion this is almost always possible. The psychological origin of the trouble should not be discussed until the patient has greatly improved and often simple psychological explanation without any deep analysis is all that is required. It is essential to interview the parents or relatives, who are often intensely concerned at the patient's refusal of food, and it is important to ensure a sensible and not over-anxious attitude to the patient's illness once she has recovered and returned to her home. Special diets, organotherapy, including gonadotrophic and pituitary hormones, the use of insulin to stimulate the appetite and the administration of vitamins are of little use in the treatment of anorexia nervosa.

NAUSEA

Nausea most commonly precedes vomiting, and in this case is relieved when the stomach is emptied. Though primarily a gastric symptom, it is often accompanied by malaise, sweating, salivation and faintness. When associated with headache it is generally a result of migraine. Association with vertigo points to vestibular disease, as in *Ménière's syndrome* and *sea sickness*. It may occur as an independent symptom in chronic gastritis, chronic cholecystitis and in carcinoma of the stomach. It is sometimes the most prominent symptom in early tuberculosis and in the first weeks of pregnancy. It may occur in nephritis and infections of the urinary tract, and in men it may result from prostatic disease, in these conditions it is often an indication of the onset of uremia, of which it may be the first symptom. All these possibilities should be excluded before regarding it as of nervous origin, but there is no doubt that it is not infrequently a hysterical symptom and due to the perpetuation by auto suggestion of nausea which originally resulted from the emotion of disgust, although the actual exciting incident may have been forgotten. In such cases the nausea often serves the subconscious purpose of providing the patient with a means of escape from some difficult situation or uncongenial occupation. Whatever its cause but especially when it is nervous in origin, nausea is increased by anxiety and depressing emotions, and is less troublesome when the mind is fully occupied.

Nausea may be constant or periodic. It may be specially associated with the consumption of fatty food or less frequently of meat, but it is often quite independent of the kind or nature of the food taken. The patient may wake up with severe nausea, which makes it difficult for him to eat any breakfast. He often thinks it is due to some disease of the stomach, and he consequently reduces the amount of food he takes, severe loss of weight may result.

Experimentally it has been shown that stimuli which cause nausea lead to interruption of peristalsis with diminished muscular tone, diminished secretion of hydrochloric acid, increased secretion of mucus, and pallor of the gastric mucous membrane, together with salivation, sweating and tachycardia followed by bradycardia. The motor changes are not a result of the nausea, as they precede its development, but are an important factor in its production.

GASTRIC FLATULENCE · AEROPHAGY

Flatulence, or the presence of excess of gas, may occur simultaneously in the stomach and the intestine, but in many cases it is confined to the stomach or to some part of the intestines.

Ætiology.—Gastric flatulence may be caused by (a) excessive production of gas by fermentation or putrefaction, (b) the introduction of excess of air by air swallowing (aerophagy), (c) deficient absorption, (d) deficient elimination.

(a) Achlorhydria may be associated with the formation of a small quantity of gas by bacterial activity, but this is very rarely sufficient to cause discomfort. In pyloric carcinoma, achlorhydria is associated with severe gastric stasis, and a considerable excess of foul gas may be produced. Offensive belching may occasionally be the first symptom of a gastric growth, but it may also occur in non-malignant pyloric obstruction. A true faecal smell in the gas brought up is found, with faecal vomiting in the late stages of intestinal obstruction.

(b) Aerophagy is the commonest cause of flatulence. It is often associated with nervous dyspepsia, but it is equally common in organic diseases, especially cholecystitis and less frequently gastric and duodenal ulcer, the pain in angina pectoris frequently causes it. The patient feels discomfort in the stomach, which he thinks is due to "wind", and which he imagines he can "disperse" by eructation. As there is really no excess of gas present, the attempt proves unsuccessful and results in the swallowing of air. After half a dozen or more attempts have been made without success, air being swallowed on each occasion, the stomach becomes distended with air, which is noisily expelled. The excessive salivation, which often occurs in gastric disorders associated with hyperchlorhydria, and in septic conditions of the mouth and naso-pharynx, also leads to flatulence, as air is swallowed with each mouthful of saliva. The severest cases of aerophagy occur independently of dyspepsia in intensely neurotic women, the symptom is then hysterical. A little saliva with a large quantity of air is swallowed until the stomach is distended, when it is noisily pumped backwards and forwards between the stomach and œsophagus by spasmodic movements of the diaphragm, and is then expelled with loud reports. This may continue periodically for many hours at a time and frequently repeated eructations make the diagnosis of aerophagy certain, as fermentation cannot give rise to so large a quantity of gas. In some cases the patient takes obvious pleasure in the performance. The gas expelled in aerophagy is odourless and may be brought up at any time of day or—very commonly—night. Eructation occurring before breakfast in the absence of pyloric obstruction is always due to swallowed air as there is nothing in the stomach from which gas could be produced. The diagnosis of aerophagy can be confirmed by radiography, whereby it is easy to watch the air being swallowed or expelled.

(c) In portal hypertension with cirrhosis of the liver, congestive heart failure, and chronic bronchitis and asthma, swallowed air and the gases produced by fermentation are insufficiently absorbed and flatulence results. In cardiac failure treatment with digitalis may give complete relief.

(d) In rare cases a valvular mechanism is set up at the cardia, which does not impede swallowing but prevents the passage of gas in the opposite direction. This *aërogastric bloquée* may result from spasm of the lower end of the œsophagus associated with an œsophageal ulcer, or from a kink caused by the dislocation of the stomach from the pressure of a distended splenic flexure in intestinal carbohydrate flatulence or a distended pelvic colon in megacolon. An enormous quantity of gas may collect in the stomach, the distension of which causes great pain, which is relieved by lying down, when the gas passes on into the duodenum, or instantaneously by the passage of a stomach tube.

Symptoms.—Gastric flatulence gives rise to a sensation of fullness in the epig-

gastrium, which may extend under the left costal margin. The accumulation of gas in the stomach pushes up the diaphragm; this may cause palpitation and attacks of dyspnoea particularly in those suffering from asthma or heart disease. Flatulence may also be the immediate cause of an attack of true angina pectoris, though more frequently the angina is the cause of the aerophagy.

Diagnosis.—When a patient complains of "flatulence", it is first necessary to ascertain whether excess of gas is really present. This can be done most readily and accurately by means of radiography, as it is often difficult to distinguish by percussion whether an accumulation of gas is in the stomach or in the splenic flexure of the colon.

Pseudo-flatulence is generally due to the patient misinterpreting the sensation of fullness which is caused by the increased intragastric pressure produced by sudden distension of the stomach, with excess of food and drink which have been too rapidly consumed. There is no abdominal swelling or increase in gastric resonance, and the patient is unable to bring up any gas, though the condition is often complicated by aerophagy. The eructation of swallowed air may relieve the discomfort which prompted the aerophagy.

Excess of gas in the splenic flexure in intestinal carbohydrate dyspepsia, and in the pelvic colon in megacolon, often gives rise to a feeling of fullness in the left hypochondrium, which is mistaken by the patient for gastric flatulence and may lead to aerophagy.

Pseudo-flatulence may also be caused by *spasm of the diaphragm*. This may occur as an independent condition or as a complication of some organic disorder, such as gastric ulcer or colitis, or after a blow on the abdomen. It is also the cause of the abdominal distension in *pseudocyesis*, in which pregnancy is simulated. The spasm may be continuous and last for weeks or months. More frequently it occurs in attacks; a sensation of great distension is experienced and the abdomen becomes so protuberant that the clothes have to be loosened. The "distension" disappears as suddenly as it comes without eructation or passage of flatus. It may lead to a mistaken diagnosis of intestinal obstruction, and laparotomies have been performed in spite of the fact that the distension disappears under an anæsthetic. The lower ribs are drawn in as a result of the pull of the contracted diaphragm, and firm manipulation of the abdomen causes the abdomen to become flat and the diaphragm to rise. The absence of excess of gas in the stomach and intestines can be recognised by radiography which shows a low position of the diaphragm and shallow respiratory movements. The patient should be taught to breathe properly with his diaphragm, but improvement is often very slow.

Treatment.—The treatment of flatulence due to excessive fermentation consists in removing the cause. When flatulence is due to aerophagy, it may be only necessary to explain to the patient the cause of his trouble in order to cure him. He should be told not to eructate, however much he may desire to do so. If he finds it very difficult to restrain himself, he should open his mouth or clench his teeth upon a cork, whenever the desire is very strong, as it is then difficult to swallow air, though any excess of gas in the stomach can be expelled. When aerophagy is secondary to dyspepsia, this requires appropriate treatment. Momentary relief, sufficient to help the patient to forego eructation, can generally be obtained by sipping hot water or chloroform water, or by taking a few drops of a carminative, such as oil of cinnamon or peppermint on a lump of sugar, but the use of spirits for this purpose should be prohibited.

NERVOUS DYSPEPSIA

Ætiology.—Emotional factors may profoundly influence digestion, and the neuroses are often accompanied by visceral symptoms. Anxiety, depression and

sensations such as anger, frustration, guilt or resentment particularly affect gastric and colonic secretion and motility, and fatigue and overwork may also play a part. The type of digestive disorder produced depends upon the nature of the psychological factors at work, and the patient's own and familial make up both mental and physical.

Symptoms—The gastric symptoms in nervous dyspepsia are characterised by their extreme irregularity, the patient feeling very ill one day and comparatively well the next without any obvious reason for the change. The most constant complaint is of vague abdominal discomfort which rarely amounts to actual pain. It is generally worst in the morning and improves towards evening, but in some cases the symptoms increase when the patient becomes more fatigued as the day goes on. The discomfort is aggravated by meals, a sensation of fullness being felt as soon as a small quantity of food has been eaten, but it is often present to a minor degree all day. It has little relation to the amount or the kind of food, differing in this way from the discomfort of organic gastric disorders. It is increased by worry and excitement while some new interest, whether it be a change of surroundings, a game, a conversation, a new medicine or a new doctor, leads to its temporary disappearance. Nausea and vomiting may occur, either separately or together. Many patients complain of flatulence which is generally due to aerophagy, but may be nothing more than a sensation of fullness. Frequent noisy belching is common, especially among older patients. The appetite is diminished, though it varies considerably from day to day. Constipation is generally present and the patient often aggravates his symptoms by overdosing himself with purgatives.

Usually physical and radiological examination of the stomach shows no abnormality, though in some cases there is a rapid gastric emptying time. The symptoms may closely simulate and not infrequently precede or coexist with duodenal ulcer. The abdominal muscles may be tense so that examination is difficult, but there is never any great degree of tenderness and what is present is diffuse and variable in position rather than localised and constant. In other cases the abdominal muscles are weak and symptoms resulting from this may be added to those resulting from the neurosis.

The gastric symptoms are always associated with other nervous symptoms such as headache and insomnia and anorexia may lead to progressive loss of weight and strength. The abdominal discomfort may be accompanied by flushing of the face, palpitation and coldness of the extremities. The patient is often depressed and pessimistic, and may pay great attention to his bodily functions, frequently looking at his tongue and minutely inspecting his stools. His account of his symptoms is full of details and he often has some theory to account for them, believing himself to be suffering from some mythical disorder such as acidity, a dropped stomach or colon, mucous colitis or intestinal auto-intoxication and not infrequently he fears he has cancer. He may seek advice for dyspepsia on its own account or because he thinks that it is the cause of his purely nervous symptoms.

Treatment—The patient's confidence can be gained only after a very thorough examination. He can then be confidently told that he has no organic disease and that with perseverance he will get well. Mental and physical relaxation are usually needed but the patient frequently much exaggerates the effects of exertion on his symptoms so that he may need to be encouraged to undertake ordinary exercise. Reassurance and encouragement are essential and congenial surroundings, occupation and companionship are most important. Strict isolation is usually to be avoided. For the dyspepsia careful dieting is not necessary, though it may be difficult to convince the patient of this and a sedative such as phenobarbitone gr. $\frac{1}{2}$ three times a day, or an alkaline mixture with sodium bromide gr. 5 added, is more helpful than various digestive mixtures or tonics. With successful treatment of the underlying nervous condition the dyspepsia will usually disappear, or at least become accepted by the patient as a harmless symptom not warranting any anxiety or alarm.

HÆMATEMESIS AND MELÆNA

Ætiology—Hæmatemesis results most frequently from a chronic ulcer of the stomach, duodenum or œsophagus, or of the jejunum after gastro jejunostomy. It occurs, generally in smaller quantities, in cancer of the stomach. The term *gastrostaxis* was at one time applied to the hæmorrhage which was supposed to occur in the absence of any organic lesion. But gastroscopy and examination of fresh specimens removed at operation have proved that very small rapidly healing and often multiple erosions or acute ulcers, which readily escape detection both on external examination during an operation and at necropsy, are often present in such cases in association with gastritis, in which a spongy or polypoid condition of the mucosa may sometimes be observed. Hæmorrhage may occur in susceptible people from areas of the mucous membrane which become congested and hæmorrhagic on contact with fragments of drugs such as aspirin, or other irritants. There is no evidence that vicarious menstruation from the stomach ever occurs, although hæmatemesis is rather more common during menstruation than in the intervals. The varicose veins which develop in the œsophagus in cirrhosis of the liver may bleed, and hæmorrhage may also occur from the congested gastric mucous membrane in cirrhosis and heart failure. Bleeding from the stomach is a common symptom of splenic anæmia, even in the early stages before cirrhosis of the liver has led to portal congestion. It may also occur in blood diseases, such as leucæmia, aplastic anæmia, hæmophilia or purpura. In rare cases hæmatemesis is caused by bleeding from multiple telangiectases of the gastric mucous membrane in patients with familial telangiectasia, a condition almost invariably associated with epistaxis. Finally, blood from the naso pharynx, mouth, œsophagus and lungs may be swallowed and vomited.

Diagnosis—Direct examination of the nose, gums and pharynx excludes the possibility of the blood coming from these sources. Hæmatemesis may be distinguished from hæmoptysis by the fact that in the former the blood is generally dark, partly coagulated and mixed with more or less food, whereas in the latter it is bright red, frothy and unclotted, in the former the symptoms may point to gastric disease, in the latter to disease of the lungs or the heart, melæna is present in most cases and occult blood in all cases after hæmatemesis, and the hæmorrhage is not often repeated, whereas in hæmoptysis the stools contain no blood, and the patient generally continues to expectorate blood-tinged sputum for several days. In chronic ulcer and carcinoma of the stomach a history of other gastric symptoms can almost always be obtained, though in ulcer they may be very mild in character and of short duration. In cirrhosis of the liver, symptoms of gastritis and hepatic insufficiency are often present, and the liver may be hard and enlarged. When hæmatemesis occurs without other symptoms, the possibility of an idiosyncrasy to aspirin should be considered. This is probably the explanation if the patient has taken aspirin shortly before the hæmorrhage, especially if he has swallowed it as an intact or broken tablet and not as powder. Otherwise gastritis with an acute ulcer or erosion is generally present, if splenic anæmia can be excluded by the absence of splenomegaly and leucopenia, the hæmorrhagic diathesis by absence of purpura or bleeding from other mucous membranes and the presence of a normal number of blood platelets and normal bleeding time and familial telangiectasia by absence of epistaxis and telangiectasia of the face. Barium meal examination should always be carried out, but not before 10 to 12 days after a hæmorrhage of any severity.

The only reliable method of measuring the quantity of blood lost is to estimate the total volume of the erythrocytes (V_e) and of the plasma (V_p) of the blood. It is unfortunate that such examinations can be carried out only at well-equipped hospitals, as observations on blood pressure, pulse rate and percentage of hæmoglobin are notoriously difficult to interpret. The immediate result of a large hæmorrhage

is to reduce the Vc and Vp without altering the hæmoglobin percentage. Only after a variable period does the blood take up enough fluid to restore the original Vp, thereby diluting the hæmoglobin sufficiently for its estimation to give a true index of the severity of the hæmorrhage, always provided this has ceased. New blood corpuscles then slowly form, with gradual restoration of Vc and hæmoglobin. The final plasma volume is very constant and in 50 per cent. of cases the plasma is fully diluted by the time the patient is admitted to hospital; in the remainder the period varies, the maximum being 72 hours for full dilution. There are no clinical means of determining that hæmorrhage has ceased, the signs generally regarded as indicative of hæmorrhage being, in fact, the manifestations of hæmorrhagic shock, and in the absence of external evidence of bleeding it may be impossible to be certain whether a falling hæmoglobin percentage indicates continuing hæmorrhage or blood dilution.

Prognosis.—The mortality among patients with hæmorrhage from a peptic ulcer is between 3 and 10 per cent. Of Hurst's cases admitted to Guy's Hospital on account of hæmorrhage, 4.8 per cent. died. In recent years the use of drip transfusions and fuller diets have reduced the mortality, which is also closely related to age. Thus, in Avery Jones' series the mortality under 45 years old was 2 per cent.; between 45 and 59, 6 per cent.; between 60 and 69, 12 per cent.; and over 70, 21 per cent.

Treatment.—The patient should be kept completely at rest, but since the sheet anchor of treatment is blood transfusion, he should be moved by ambulance to hospital or nursing home, where all facilities for this are available as soon as possible, in spite of the slight added risks of transportation. In order to obtain rest and allay anxiety it is generally advisable to inject morphine, a full dose being given and repeated as necessary. The bed-pan must be used, and the patient should not at first even be allowed up for micturition. Sips of water should be given by mouth from the start, and rectal salines either by drip or in amounts of 8 to 10 oz. 4-hourly are advisable if there is any vomiting or inability to retain fluids easily by mouth. No laxatives should be given, but if the bowels do not open spontaneously on the third or fourth day a simple saline wash-out is generally the only treatment needed.

Diet.—The high caloric diet advised by Meulengracht in Denmark in 1934 was based mainly upon the rationale of keeping the stomach full in order to reduce hunger peristalsis and so lessen the tendency for bleeding to continue. Modified feeding similar to that advised by him is generally well tolerated within 24 hours of the bleeding: it avoids any long period of starvation, aids acid neutralisation and gastric rest, and is based upon sound principles of ulcer treatment. Milk feeds with purées, soft puddings, eggs and vegetable soups, as for the Stage 1 ulcer diet may be ordered from the start of treatment, and after this increased as indicated on p. 581. At the same time, especially in older people, large feeds are inadvisable, and it is wiser at first to give only milky foods in frequent small amounts of 3 or 4 oz. rather than insist upon the fuller régime which a young and strong adult can take with advantage.

If the hæmoglobin falls to 40 per cent. or lower, the equivalent of a Vc of 700 ml., the patient should be transfused at the rate of 30 to 40 drops a minute till the hæmoglobin percentage reaches 60, the average volume required being 1500 ml. With slow transfusion (i.e. 1 litre in 4 to 8 hours) the blood pressure does not rise nor does the Vp increase above normal; the sole result is the rise in Vc, which is entirely desirable. Transfusion is required to prevent a patient from dying from anaemia; it is not essential for the restoration of the blood to the normal level, as an average gain of 1 or 2 per cent. of hæmoglobin per diem will occur when full doses of iron are given. At the same time there should be no hesitation in giving enough blood to produce a hæmoglobin percentage of 80, especially if surgical treatment is to be undertaken. The use of packed red cells minimises the risks of over-loading the circulation. For surgical treatment, see p. 586.

Iron.—Iron and ammonium citrate gr. 30, four times a day in solution is usually

well tolerated, or enteric-coated capsules of ferrous sulphate gr. 6, four times a day may be given. Intravenous injections of iron as the saccharated oxide (Ferrivenin) may be needed at first if oral iron causes vomiting or pain. The daily dose should not exceed 200 mg. Ascorbic acid mg. 200 daily should be given at the same time.

ORGANIC DISEASES OF THE STOMACH

ACUTE GASTRITIS

(a) ACUTE CATARRHAL GASTRITIS

Etiology.—Acute gastritis is caused by irritation of the mucous membrane of the stomach, varying in degree according to the intensity and duration of the irritation. Most frequently such irritation is due to exogenous causes of which bad eating habits, the lack of teeth or dentures and the bolting of large indigestible meals, with excesses of alcohol, condiments or badly chewed food are the most important. The swallowing of infective material from the nose, sinuses, gums, teeth or purulent sputum from the chest are further causes. In many cases the irritant is a toxic product of bacterial activity in food, several individuals being often affected simultaneously; such infection may belong to the *Salmonella* group of organisms or arise from food contaminated by staphylococci during its preparation as, for instance, by a cook with a discharging whitlow on the finger. Chemical irritants in food are less frequent than bacterial, but drugs such as aspirin, salicylates and quinine are common causes. Tobacco chewing is another.

Corrosive poisoning due to the swallowing of violent irritants such as lysol, carbolic acid, arsenic or corrosive sublimate either accidentally or suicidally causes an intense (phlegmonous) gastritis (*q.v.*).

Endogenous causes of acute gastritis include the toxic products of uræmia, and

Diagnosis.—In severe pyrexial cases the symptoms may simulate the onset of an acute infection, such as typhoid fever, but the rapid improvement soon makes the diagnosis clear. Cases occur in which the pain, tenderness and rigidity are so severe that considerable doubt may be felt at first whether a gastric ulcer may not have perforated.

Prognosis.—Recovery generally takes place within 24 or 48 hours, but in toxic and infective cases the acute symptoms may persist for several days, at the end of which they may suddenly disappear. The condition often passes into chronic gastritis, which may remain completely latent, though the stomach is often abnormally irritable for a considerable time.

Treatment.—The patient should be kept warm in bed with hot applications to the abdomen. If the stomach is not spontaneously emptied, vomiting should be induced by drinking half a pint of warm water, in which a teaspoonful of sodium bicarbonate has been dissolved; when this fails, the stomach should be washed out.

A saline aperient should be administered if there is constipation. No other drugs should be given except in the rare cases in which very severe pain persists after the stomach is empty, when an injection of morphine may be required. Nothing but water, which may be flavoured with tea, should be taken until all the acute symptoms have disappeared. Sweetened arrowroot made with water may then be given, and, as the appetite returns and the tongue cleans, dilute citrated milk, farinaceous food, eggs, and lastly, fish, chicken and meat can be added to the diet.

(b) ACUTE SUPPURATIVE GASTRITIS

Ætiology.—This very rare disease is due to the invasion by streptococci or less frequently pneumococci, staphylococci or *Bact. coli*, of the submucous tissue through a carcinomatous ulcer, or still more rarely through a chronic ulcer or the wound left after an operation on the stomach. In exceptional cases the point of invasion cannot be recognised. The condition may also occur in pyæmia, anthrax and smallpox.

Symptoms.—Epigastric pain and tenderness are severe. Vomiting is always present. The vomitus may contain pus owing to the rupture of a localised abscess into the lumen of the stomach. Peritonitis generally supervenes in the course of 2 or 3 days. The general symptoms present are those common to severe infections.

Prognosis.—A local submucous abscess may burst inwards and spontaneous recovery follows, but more commonly it ruptures outwards, producing general peritonitis. Diffuse suppurative gastritis always ends in peritonitis.

Treatment.—In very rare cases a localised abscess has been treated successfully by operation.

(c) ACUTE PHLEGMONOUS GASTRITIS

Ætiology.—Phlegmonous gastritis results from the ingestion of irritant poisons, such as concentrated acids and alkalis, arsenic and antimony.

Symptoms.—The local symptoms are similar to those of acute suppurative gastritis, except that the vomited matter frequently contains blood and sometimes sloughs. The patient is collapsed and may become comatose, the symptoms depending upon the nature of the poison.

Prognosis.—Death frequently occurs from shock, general peritonitis or the effect of the poison on other parts of the body. If the patient recovers, achylia gastrica is almost always present as a result of atrophy of the mucous membrane, and pyloric obstruction frequently develops.

Treatment.—An attempt should be made to dilute and neutralise the poison. When this is impossible the stomach should be washed out. Morphine should be injected to relieve pain and to keep the patient quiet.

CHRONIC GASTRITIS

Ætiology and Pathology.—Chronic gastritis was formerly believed to be a very common condition, largely owing to the work of Professor Knud Faber on gastric secretion, and later of Schindler and his collaborators with the gastroscope. In recent years greater experience of gastroscopic studies together with a fuller knowledge of the secretory activity of the stomach have greatly altered our conception of this condition. Many changes in the gastric mucosa previously regarded as due to chronic hypertrophic or atrophic gastritis have now been shown to be merely temporary variations from the normal, caused by everyday emotions or by the normal stimuli of food or drink. The observations of Wolf and Wolff (see p. 557) showed conclusively that the gastric mucous membrane normally became hyperæmic, turgid and engorged, with an increase in mucus and acid secretion, under emotional stimuli such as resentment or anxiety, whilst that of fear caused pallor of the mucosa and diminished secretion.

It is probable that the three pathological types of gastritis—superficial, hypertrophic and atrophic—described by Schindler and others are in fact only stages of one process which may have a number of causes. Some cases, probably quite uncommon, have no specific cause that we can determine. In others the same causes are at work as in acute gastritis, either repeated or of longer duration, with in addition an important group of cases due to mechanical pyloric obstruction. Any cause of pyloric stenosis, whether due to cicatrization of an ulcer, to simple pyloric spasm, to a carcinoma or to congenital stenosis, may equally lead to chronic gastritis. Some gastritis is present around all gastric ulcers, and it is an almost constant finding at the site of a gastro-enterostomy. Full correlation of gastroscopic, histological and clinical findings in cases of gastritis is not yet possible, but pathologically a hypertrophic and an atrophic gastritis may be distinguished, the former showing increased vascularity, œdema, a thickened mucous membrane with very rarely polypoid hyperplasia, the latter avascularity and a thin aplastic mucosa.

Symptoms.—Changes in the gastric mucous membrane or in the secretions of the stomach may exist with no demonstrable symptoms whatsoever, and detailed descriptions of the symptomatology of various types of gastritis are quite without accurate clinical foundation. The symptoms of hypertrophic (acid) gastritis if they occur at all are similar to those of chronic peptic ulcer, but it is rare for any symptoms to arise unless an ulcer is in fact present. In the exceptional cases in which symptoms occur in the absence of a chronic ulcer they are indistinguishable from those of duodenal ulcer, and a diagnosis can be made only when a radiographic examination shows that there is no constant gastric or duodenal deformity in spite of the presence of typical symptoms, tenderness and rigidity, associated with hyperchlorhydria and sometimes occult blood in the stools. Rigidity, thickening and coarseness of the mucosal folds as demonstrated by radiological study of the mucosal relief pattern on examination with a thin layer of contrast medium may, in expert hands, give useful confirmatory evidence of gastritis. Hæmatemesis may occur from an acute ulcer or erosion, which gives no radiological signs of its presence but can

Pain never occurs in uncomplicated atrophic gastritis, but slight epigastric discomfort, generally described as fullness, pressure or heaviness, is common. It follows immediately after meals, and may last several hours in the small group of cases in which evacuation is slow. It is often partially relieved by belching, but frequent attempts to eructate may result in aerophagy. In spite of the presence of achlorhydria, heartburn and sour regurgitation, which are relieved by sodium bicarbonate, may occur. Tenderness is slight and ill-defined, and there is no rigidity.

Vomiting occurs if nausea is severe, or if the epigastric discomfort is unusually prolonged. It is often to a large extent voluntary, the patient having discovered that it gives relief. The vomited material generally consists of undigested food mixed with mucus and often with bile, but the morning vomit of alcoholics is an alkaline, mucous fluid, composed of swallowed saliva and secretion from the inflamed pharynx and œsophagus.

Constipation is generally present, but in one group of cases chronic or intermittent attacks of diarrhœa occur, and may persist for many years with little or no gastric symptoms to suggest its gastrogenous origin (see p. 610).

The tongue is generally clean, but in alcoholic gastritis it is often furred and the patient complains of an unpleasant taste in his mouth. When achlorhydric gastritis is associated with anæmia, whether simple or Addisonian, atrophy of the filiform papillæ is often present, sometimes accompanied by recurrent attacks of sub-acute glossitis, in which the patient complains of soreness of the tongue.

The size and tone of the stomach are generally normal, but evacuation is usually rapid. In the achlorhydria following the gastritis of an acute infection it may be slow owing to the rapid exhaustion of peristalsis, the radiogram showing periods of complete inertia alternating with periods of normal activity, but there are no characteristic findings which enable the radiologist to diagnose the condition. The test meal may give some indication of the presence, type and degree of gastritis. In most cases mucus is present in the resting juice and in each fraction, and the curve of total acidity remains moderately high above the base line. In advanced cases, in which atrophy of the mucous membrane has occurred and involved the superficial mucus secreting cells as well as the tubules, mucus is absent and the total acidity is much reduced. So long as mucus is present, treatment is likely to result in recovery of the power of secreting free acid, but this very rarely occurs in the absence of mucus. In the former case, but not in the latter, an injection of histamine when fasting or at the end of the test meal is generally followed by the secretion of free acid.

Treatment.—All possible causes of gastritis should be removed as far as possible. The teeth should be put into good condition and artificial ones supplied when necessary. Septic tonsils should be enucleated, and nasal infections treated. If the tongue is furred it should be frequently scraped, and sufficient dry food should be given to promote an adequate secretion of saliva. The food should be thoroughly chewed and eaten at regular times, the last meal at least 2 hours before going to bed. The patient should rest for half an hour after meals, and, if he is tired, for a short time before meals also.

Alcohol should be entirely prohibited, and smoking strictly limited. Tea must be weak and freshly brewed, and coffee only drunk if mixed with at least an equal quantity of milk. Meat should be allowed at only one meal a day and should be very tender. Ripe cheese, coarse bread substitutes and oatmeal, skins and pips of fruit, salads, pickles and green vegetables, except as purées, should be prohibited. A purée of spinach is particularly useful, as it contains a histamine-like substance which is a stimulant of gastric secretion, even when taken by mouth. In severe cases, especially if the stools contain occult blood, it is best to give the strict ulcer diet (p. 583) for the first week or two, but with 2-hourly instead of hourly feeds.

If much mucus is present in the test meal, Hurst recommended that the stomach should be washed out every morning with dilute hydrogen peroxide, beginning with

Pain never occurs in uncomplicated atrophic gastritis, but slight epigastric discomfort generally described as fullness, pressure or heaviness, is common. A purée of spinach is particularly useful, as it contains a histamine like substance which is a stimulant of gastric secretion, even when taken by mouth. In severe cases, especially if the stools contain occult blood, it is best to give the strict ulcer diet (p. 583) for the first week or two but with 2-hourly instead of hourly feeds.

If much mucus is present in the test meal, Hurst recommended that the stomach should be washed out every morning with dilute hydrogen peroxide, beginning with

a teaspoonful and increasing gradually to a tablespoonful to the pint. The nascent oxygen given off dislodges the mucus from the surface of the mucous membrane, and at the same time acts as an antiseptic and perhaps stimulates the secretion of gastric juice.

In old and debilitated patients, for whom lavage is too strenuous a treatment, a teaspoonful of sodium bicarbonate in a glass of soda water, drunk whilst fasting first thing in the morning, has a similar though less powerful action.

Hydrochloric acid may be helpful, and a teaspoonful of the dilute acid (B.P.) in about 5 oz. of water to which sugar and the juice of an orange or of any other fresh bottled or stewed fruit have been added, may be drunk before breakfast and as a beverage with lunch and dinner, gr. 5 of pepsin may be added to the two latter doses.

The bowels should be kept regular by taking honey, fruit from which pips and skins have been separated, and green vegetable purees. If necessary, liquid paraffin can be given, but irritating aperients should be avoided.

GASTRIC AND DUODENAL ULCER

Ætiology—Gastric and duodenal ulcer, though similar both pathologically and clinically, must be regarded as essentially different in several important aspects. Chronic gastric ulcer occurs with equal frequency in males and females, but duodenal ulcer is about four times more common in males. Duodenal ulcer occurs between three or four times as frequently as gastric ulcer in the higher social grades, and between three and eight times as frequently in most British hospitals. The mortality from gastric ulcer is some two to three times greater in the lower social classes than the higher, whilst from duodenal ulcer there is little difference between the various social levels. Duodenal ulcer is increasing in incidence, whilst gastric ulcer is not, ambitious, energetic professional or business men tend to develop the former, whilst poorer, badly fed and less active people, women or men, develop the latter. Hæmorrhage and perforation are frequent in duodenal ulcer, but less frequent in gastric ulcer. The main causes of duodenal ulcer lie essentially in the make-up and temperament of the individual and his over active stomach, whilst in gastric ulcer the most important causes lie in local mucosal irritation, associated with nutritional factors and environmental conditions.

A chronic gastric ulcer was found by Stewart in 2.2 per cent. and a chronic duodenal ulcer in 3.8 per cent. of 4000 consecutive necropsies. The scars of healed ulcers were found in the stomach in 2.3 per cent. and in the duodenum in 3 per cent. of the series. Chronic ulcers or scars were found in the stomach and duodenum of the same individual in 0.5 per cent. Thus, a chronic ulcer, healed or unhealed was found in 9.5 per cent. of post mortems, and it may therefore be assumed that about 10 per cent. of all individuals suffer at some time in their lives from a chronic gastric or duodenal ulcer.

Though chronic ulcer is rarely diagnosed in children, the symptoms date from the age of 12 to 18 in some 20 per cent. of cases recognised later in life, and an onset during early school age is by no means rare. It is uncommon for a duodenal ulcer to develop after the age of 50 in women, but in men the first symptoms not infrequently appear between 50 and 60 and occasionally even later.

Hurst gives the average age of onset of gastric ulcer in women as 26 and in men 45, with that of duodenal ulcer as 38 in both sexes, but in my experience the average age for duodenal ulcer has been lower.

Chronic ulcer frequently occurs in several members of a family in one or more generations. The ulcer is generally either gastric or duodenal in all the affected members, but a familial incidence is relatively more common in duodenal than in gastric ulcer. In familial cases the symptoms tend to begin at an earlier age than

usual, and there is a great tendency for anastomotic ulcers to form after operation. There is also a special tendency in some families for the ulcers to be complicated by hæmorrhage.

Pathogenesis—The peculiar type of ulcer found in the stomach and duodenal bulb occurs nowhere else except in the part of the jejunum immediately distal to the anastomosis after gastro-jejunostomy and partial gastrectomy, in the lower end of the œsophagus when relaxation of the cardiac sphincter allows gastric juice to regurgitate, and also in association with heterotopic gastric mucosa in the lower extremity of the œsophagus and in Meckel's diverticulum. The one common feature of these situations is the presence of acid gastric juice, and owing to the fact that gastric pepsin plays some part in their causation by digesting dead or ischæmic mucous membrane such ulcers are termed *peptic*.

Acute and chronic gastritis are frequently associated with localised loss of the superficial tissue, which varies in size from minute erosions only recognisable on microscopical examination to acute ulcers easily recognisable with the naked eye. Acute ulcers occur in any part of the stomach, in the duodenal bulb, and in the region of the anastomosis after gastro-jejunostomy or partial gastrectomy. The majority of erosions and acute ulcers heal rapidly, but in certain individuals and under certain circumstances they may become chronic. The various conditions already described which give rise to gastritis can thus be regarded as factors in the development of chronic ulcers.

Long hours without food, especially during periods of nervous strain and fatigue, or hastily eaten meals taken without mental relaxation, are particularly frequent antecedents in cases of duodenal ulcer. Though all occupations are liable to peptic ulcer, transport and lorry drivers, doctors, waiters and business men are amongst those especially affected. Frequent changes of shifts from day to night work and the irregular hours of meals sometimes necessary in certain industries may also be predisposing factors. Some evidence suggests that excessive smoking increases the tendency to develop a chronic ulcer, perhaps partly by the frequent tendency for heavy smokers to substitute a cigarette for a meal. As indicated on p. 557, the mucous membrane of the stomach becomes thick and hyperæmic, and muscular activity and the secretion of gastric juice are increased during periods of anxiety and with frustration and annoyance. This congested mucous membrane is more vulnerable to slight injury and, if the protective mucus is wiped away, an ulcer may develop, which explains why emotional upsets frequently give rise to recurrence of ulceration. Chills and acute upper respiratory infections may also bring on relapses, which are particularly liable to occur at the change of the season in spring and autumn. In rare cases duodenal ulceration follows extensive burns (Curling's ulcer), possibly as a result of the histamine substances produced in the skin stimulating excessive gastric acid secretion.

ACUTE GASTRIC AND DUODENAL ULCER

Symptoms—An acute ulcer gives rise to no symptoms unless it causes hæmorrhage, which is often profuse but very rarely fatal, or, in very exceptional cases, perforation. Hæmorrhage or perforation occurring without any previous indigestion is thus frequently due to an acute ulcer. The gastritis, of which it is a complication, is often completely latent, but it may give rise to any of the symptoms described on p. 573.

Acute duodenal ulcer is the most common cause of *melena neonatorum*. Less frequently it causes hæmatemesis in infants, and it may also give rise to vomiting and marasmus without obvious hæmorrhage during the first 4 months of life.

Prognosis—Acute ulcers can develop into chronic ulcers, but the majority heal rapidly, leaving no trace of their presence. There is a great tendency to relapse, but the patient is able to take a full diet without discomfort between the attacks.

Treatment—For the treatment of the hæmorrhage, see Hæmatemesis. All possible causes of gastric irritation should be dealt with, the after-treatment being that of chronic ulcer. The patient should be kept in bed on a strict ulcer diet until no occult blood has been present in three consecutive stools. The diet can then be rapidly increased.

CHRONIC GASTRIC ULCER

Symptoms—The onset is generally insidious, the symptoms first appearing after big or indigestible meals. The pain, which is often burning in character and may be very severe, is situated in the middle or slightly to the left of the epigastrium and may radiate upwards and to the back, it is much increased by indigestible food and generally disappears with a milk diet. In ulcers situated near the cardia it begins almost immediately after meals, and in prepyloric ulcers 2 or 3 hours after, intermediate intervals often indicating an ulcer on the lesser curvature. The pain generally disappears spontaneously after about an hour. It is completely relieved by vomiting and by alkalis, but, as a rule, only partially by food. Some relief may follow lying down and the application of warmth to the epigastrium.

A small area of tenderness, the position of which is constant for each case, may be present in the epigastrium. It is more severe than in any other gastric disease, it is most marked in the presence of spontaneous pain. It is often associated with rigidity of the left rectus.

With increasing pain vomiting appears, it occurs at the height of the pain, a small quantity of acid fluid with a little well-digested food being brought up. When the pain is severe, vomiting is often induced by the patient and may eventually develop into a voluntary act.

Occult blood is almost always found in the stools and vomited material, but disappears slowly when the patient is dieted. In about 25 per cent of cases obvious hæmatemesis occurs at some period of the illness. When the blood is abundant it is bright in colour and the stools are tarry, when less abundant it is coffee coloured and mixed with food, and is recognisable in the stools only by chemical and spectroscopic examination. Melæna may also occur without hæmatemesis, but much less frequently than in duodenal ulcer.

The appetite is good at first and the tongue is clean, but fear of pain may lead to diminished intake of food with consequent loss of weight and weakness. In some cases, however, the relief given by food encourages the patient to eat heartily. Constipation is commonly present.

In uncomplicated cases there may be some delay in evacuation owing to reflex spasm of the pyloric sphincter, this is especially frequent with ulcers near the pylorus, but occasionally with those on the lesser curvature also gastric stasis up to 12 or even 24 hours may occur. A spasmodic narrowing is sometimes observed radiographically in the centre of the stomach when the ulcer is situated on the lesser curvature (see p 559). Conclusive evidence as to its size and position is almost always obtainable by the discovery of a "niche" formed by the crater of a chronic ulcer, which is filled with the opaque salt and is the site of the maximum tenderness. If the examination is postponed for 2 or 3 weeks on account of hæmorrhage, it is often impossible to recognise a niche, though the ulcer has not yet healed.

A test meal gives no constant result, but in long standing cases hypochlorhydria and even achlorhydria may be present, these are caused by the associated chronic gastritis, and a test meal given after the ulcer has healed shows an increase in acidity and even hyperchlorhydria, the treatment having led to disappearance of the gastritis.

Diagnosis—A presumptive diagnosis of gastric ulcer may generally be made from the symptoms, especially if hæmatemesis has occurred, but in its absence it is impossible to be certain without the aid of radiography. If the latter does not reveal

the presence of a niche, a chronic ulcer can, as a rule, be excluded, but gastroscopy occasionally reveals a small chronic ulcer which has escaped recognition with the radiograph. In carcinoma of the stomach anorexia is likely to be present and a palpable tumour may be found, which is far less frequent in ulcer. Anæmia may occur in both. The discomfort of gastric cancer, even in its early stages, usually begins directly after meals and is more persistent than the pain of ulcer, as may be that of chronic gastritis. Free hydrochloric acid is absent in the test-meal in about 50 per cent. of cases of cancer, and occult blood is usually present in the stools continuously. The gastric symptoms associated with cholecystitis may simulate ulcer, but the relation of the pain to the nature and time of meals is less regular, and less relief is given by alkalis; tenderness is present over the gall-bladder in addition to the epigastrium. For the differential diagnosis of other conditions causing hæmatemesis, see page 569, and for the distinctions between œsophageal and duodenal from gastric ulcer, see pp. 549 and 579.

Complications.—Perforation of an anterior ulcer leads to general peritonitis (*vide* p. 712). It is rare for a gastric ulcer to be situated sufficiently near the pylorus to cause obstruction on healing, but the swelling and œdema round a prepyloric ulcer together with reflex interference with the normal relaxation of the sphincter often result in temporary pyloric obstruction, which disappears when the ulcer heals as a result of treatment. Recurrent cicatrization over a period of many years of a large and very chronic ulcer in the body of the stomach in women may cause hour-glass constriction. Very chronic gastric ulcers, especially in the prepyloric region, may rarely become carcinomatous (p. 590), but such ulcers may form definite tumours without being malignant. The earlier onset and absence of remission of pain, with the occurrence of anorexia and progressive loss of weight in the absence of alkalosis, should suggest the possibility of malignant degeneration.

CHRONIC DUODENAL ULCER

Symptoms.—The earliest symptom of duodenal ulcer is generally a sense of discomfort or fullness 3 hours after the largest meals. This is gradually replaced by pain, which occurs between 1 and 4 hours after every meal, the interval being longer the larger the meal. In the early stages, however, it is likely to occur only after the heaviest meal. It frequently wakes the patient in the early part of the night, particularly if the last meal was finished less than 3 hours before going to sleep. It is generally situated in the middle line rather nearer the umbilicus than the ensiform cartilage; it may radiate to the right or be situated on the right side only; less often it is on the left. The pain is at first associated with a feeling of hunger and is relieved by taking food; it is therefore commonly known as "hunger pain". It is also relieved by alkalis and when the stomach is emptied by vomiting, which is, however, rare in uncomplicated cases, though regurgitation of mouthfuls of scalding, very acid, fluid may occur when the pain is at its height.

Constipation is almost always present. The appetite remains good, and the patient does not lose weight or strength.

Periods of hunger pain lasting some weeks or months alternate with periods of more or less complete freedom from symptoms. The attacks are more common in cold weather than in hot, but the autumn and early spring are generally more trying than winter. Attacks are liable to be brought on suddenly by worry, exposure to cold, acute naso-pharyngeal or bronchial infections, indigestible meals and excessive smoking or drinking.

In the majority of cases occult blood is found in the stools. Severe hæmorrhage occurs in about 25 per cent. of cases: it always results in mælena and may also give rise to hæmatemesis.

In early cases radiography shows that the stomach is often of the short high type

and empties itself with unusual rapidity. In more chronic cases reflex spasm of the pyloric sphincter may lead to delayed evacuation and consequent increase in size of the stomach, the greater curvature of which then reaches below the umbilicus. Irregularity in the outline of the duodenal bulb, due partly to the deformity caused by the ulcer itself and partly to spasm, is always found. It affords evidence that an ulcer has been present, but unless it is tender or a definite niche is seen, may only indicate the scar of a healed ulcer. The niche formed by an ulcer on the lesser curvature of the duodenal bulb can be recognised in the silhouette of the bulb, one on the anterior or posterior wall can only be recognised when a radiograph is taken whilst the bulb is being compressed. A test meal generally shows hyperchlorhydria with a climbing curve, and excess of acid juice in the fasting stomach and after all the starch has left indicates that this is associated with hypersecretion. The nocturnal fasting secretion shows a continuously high acid level.

Diagnosis—When the symptoms have been present for a short time only, an actual ulcer may not be present, but there is a pre-ulcerative duodenitis, which may be associated with a rapidly emptying duodenal bulb, no constant radiographic deformity and no occult blood in the stools. It is likely to result in ulcer if not adequately treated. Excessive smoking, over-fatigue and anxiety may give rise to almost identical symptoms in individuals with hypersecretion.

The diagnosis from gastric ulcer depends upon the later onset of pain, the greater relief on taking food, the rarity of vomiting, the greater frequency of a climbing hyperchlorhydric curve obtained with a fractional test meal, the frequent situation of pain and tenderness to the right of the middle line, the more frequent periods of complete freedom from symptoms, and the results of radiogram examination, which occasionally, however, reveals the presence of an ulcer in the stomach as well as in the duodenum. Hæmatemesis without melæna is much more common in gastric than in duodenal ulcer, and melæna alone is more common in duodenal ulcer. The symptoms may closely resemble those of cholecystitis, but in the latter condition the pain is much less regular in its time relations, the tenderness is over the gall bladder, and evidence of gall bladder disease is obtained by cholecystography and duodenal intubation.

Carcinoma of the pylorus may closely simulate duodenal ulcer, but the symptoms are more continuous, there is often more local tenderness on palpation, and there is much less relief with food. Recurring attacks of chronic relapsing pancreatitis are also difficult to distinguish from ulcer (p. 705), but there is usually more vomiting, and loss of weight with pain severe enough to require morphine, usually radiating to the left side and often to the back.

Complications—The inflammatory swelling and spasm around a large ulcer may lead to *obstruction*, the first symptom of which is generally vomiting. This may rapidly clear up with medical treatment, but after a number of relapses an ulcer may heal with much scarring causing a cicatricial pyloric stenosis which can only be treated by surgical operation. *Perforation* may occur, and lead to general peritonitis, or less commonly to a localised abscess. Sub-phrenic abscesses due to duodenal ulcer are always to the right of the suspensory ligament and may contain gas, unlike those secondary to appendicitis. *Penetration* of the ulcer into neighbouring organs—chronic perforation—is a common complication particularly involving the pancreas. Dense adhesions may form and the surrounding mass of fibrous tissue may become so hard and dense that it is difficult to distinguish it from malignant disease. Duodenal ulcers however, never are and never become malignant. *Hæmorrhage* is a serious complication and may occur at any period of an ulcer history. It is often followed by a temporary relief of symptoms, but may in a few cases arise without any previous pain at all.

The long continued use of alkalis and loss of chloride by persistent vomiting may give rise to alkalosis, the first symptoms of which are anorexia, irritability and de-

pression, which may suggest the onset of malignant disease. Later, twitching and even convulsions, coma and death may occur, the condition being indistinguishable from uræmia. The blood urea is always increased (non renal azotæmia). Recovery takes place when no more alkalis are taken and extra chloride and fluids are given.

Prognosis—Prognosis as regards life in cases of peptic ulcer is on the whole good, and few of those who suffer from it actually die of the disease. Many active men live full and successful lives in spite of persistent recurrence of symptoms. Gastric ulcer mortality is uniformly higher at all ages in both sexes than is that of duodenal ulcer, though perforation and hæmorrhage are both more frequent in duodenal than in gastric ulcer, the prognosis of these complications is graver at and after middle age than below it, especially amongst the well-to-do.

Not less than 1 in 5 of all duodenal ulcers bleed or perforate before the patient reaches the age of 40.

As regards relapse it is doubtful if more than 50 per cent of all cases treated medically remain free of symptoms for longer than 2 years, and the results of simple gastro-enterostomy for duodenal ulcer are very much the same. The operative mortality for gastro-enterostomy is about 2 per cent., and that for gastrectomy between 3 and 8 per cent in average hands. Permanent freedom from symptoms following the bigger operation may, however, be expected to result in suitably selected patients in some 75 to 95 per cent of cases, if the operation is performed sufficiently radically and by a skilled surgeon.

Social and economic factors, family history and the psychological make up of the patient all influence prognosis and must be carefully considered before any decision to advise operation is made. The best prognosis is obtained by the careful co-operation of physician and surgeon, and meticulous pre-operative preparation with good after care of the patient, if operation is undertaken.

TREATMENT OF CHRONIC GASTRIC AND DUODENAL ULCER

GENERAL PRINCIPLES—The object of dietetic and drug treatment is to reduce the quantity and acidity of the gastric juice and to rest the motor activity of the stomach, especially over vigorous peristalsis, as much as possible. Free hydrochloric acid delays the healing of an ulcer, whatever additional factors may have contributed towards its production in the first instance. As much food as possible is required to maintain the patient's nutrition, especially when he has lost weight, as is often the case. The stomach should not be allowed to remain long empty but kept moderately filled with food which is as little irritating either mechanically or chemically as possible.

Many ulcers heal spontaneously, as evidenced by the number of healed scars which are found post mortem in individuals who have never had any special treatment during their lives. Others will certainly heal rapidly if a patient is only able to have a period of mental contentment, a change of environment and frequent regular meals, with a diet which merely avoids the extremes of unsuitable foods. It is also abundantly proved that perfect healing can be achieved without the use of a single dose of alkali or other medicine.

In spite, however, of these facts relapse is certain unless healing is complete, and it is always wise to insist upon a thorough treatment if this can possibly be given. At the same time it must be realised that the psychological make up of the patient is important, and to insist upon a busy anxious man giving up his work completely and going to bed at a time which will involve serious financial or other anxieties, is to handicap treatment from the start by producing an atmosphere of frustration, irritation and resentment. It may often, therefore, be wiser to temporise for a time and adjust the treatment as far as possible to the temperament of the patient. As a general rule ambulant treatment at home is likely to fail, and whenever possible the patient should be admitted to hospital or a nursing home, both to ensure that

treatment is properly carried out and to provide the mental and physical rest and atmosphere of confidence and calm which it may be impossible to obtain at home.

For the first 2 to 3 weeks of treatment the patient should be kept warm in bed, but he should be allowed up to have a bath and open his bowels, the difficulties of which are much reduced if the use of the bed pan is avoided. As a rule, no smoking is to be permitted during the period of strict treatment, but exceptions may be necessary in special cases. Mental relaxation is essential, and freedom from business or family worries must be achieved if possible. Judicious regulation of any work done, visitors allowed, etc., must be adopted according to the individual, and relapse during treatment may readily follow bad news or an unpleasant interview.

The less irksome the treatment and the diet can be made the more successful is it likely to be, and many ulcer patients have proved to their physicians that they are able to heal their ulcers and remain well when eating items of food which they like and enjoy, even though they cannot do so on diets which nauseate and disgust them. When and how food is eaten is at least as important as exactly what sort of food it is. It is now recognised that it is unnecessary to adopt any "ladder" system of daily graduated increases in diet, as originally advised by Lenhartz, Sippy and others, and at all stages of treatment hunger is to be avoided, and extra milk given if it is required.

Frequent feeding is the essential factor and at the start hourly feeds (Stage 1) are often advisable or essential. In these cases 5 oz of milk, which can be flavoured with tea, cocoa or chocolate are given every even hour from waking until the patient settles for the night, an equal quantity of custard, junket or other milky food or white vegetable puree being given at the odd hours. An additional feed should be given each time the patient wakes during the night. Thin bread and butter, rusks and one or two lightly boiled or raw eggs can be added to the diet, they should be thoroughly chewed, and the fluid feeds should be slowly sipped. Apple or other fruit jelly may be used to flavour some of the feeds, and an ounce of strained orange juice should be given three times a day, 50 mg of ascorbic acid should be given twice a day. Immediately before three of the feeds half an ounce of olive oil is taken, and cream may be added to three of the other feeds if available. The oil inhibits the secretion of gastric juice, at the same time it supplies a digestible and unirritating food of high nutritive value in a concentrated form.

Not all cases require, however, such frequent feeds and many patients may be treated successfully from the beginning by 2 hourly feeds (Stage 2) in which solid meals are given at 8 a.m., 12 noon and 6 p.m., and feeds as in Stage 1 at 6 a.m. (if awake), 10 a.m., 2 p.m., 4 p.m., 8 p.m. and 10 p.m. The solid meals may consist of boiled or steamed fish, or chicken, mashed potatoes and pureed vegetables, steamed or milky puddings, toast, and pip less jam or honey, plain cake, biscuits and cream cheese. In the third stage (Stage 3) of treatment lamb, tongue, rabbit, sweetbreads and liver are added, the intervals between feeds being lengthened to 8 a.m., 10.30 a.m., 1 p.m., 3 p.m., 4.30 p.m., 7 p.m., 9 p.m., and 11 p.m.

Strict treatment should be continued until the patient has no spontaneous pain and no tenderness or rigidity on examination. Rate of progress must be judged for each case but no treatment should last less than 6 weeks and in large and chronic ulcers it may need to be 8 or 12 weeks or more. Healing will be quicker in young patients with recent ulceration, and slower in older patients or in those with a long history of relapses. In many cases Stage 2 may be adopted from the start of treatment but in others Stage 1 must be ordered for the first week or 10 days. In general Stage 2 is to be continued for a period of 3 to 4 weeks or more. On this treatment pain generally disappears within 48 hours, occult blood in the stools may persist for 1 or 2 weeks, but if it continues longer without interruption in the case of a gastric ulcer it suggests a possible malignant lesion. Radiographic control of healing is advisable, particularly in the case of gastric ulcers, but with duodenal ulcers it

is far less satisfactory as deformity of the duodenal cap due to scarring may make interpretation of the appearances very deceptive. There is no fixed rule which can decide exactly when an ulcer has fully healed, as the crater may become filled with granulation tissue so that no niche is seen with the radiographs a fortnight or more before it is replaced by mucous membrane. With gastric ulcers the gastroscope can determine exactly the stage of healing, but with duodenal ulcers this is of course impossible.

Any ulcer which fails to improve symptomatically within 4 weeks on the above regime demands a full review of the case, as it is either complicated by neurosis or other disorder (e.g. cholecystitis) or it must be considered as probably requiring surgical treatment.

ALKALIS—The use of alkalis during the period of strict treatment is probably unnecessary, and in large dosage may be actually dangerous. With hourly feeding it is better to avoid them, but with the later stages of treatment an alkaline powder given between feeds three or four times a day and last thing at night is often useful, especially if any abdominal discomfort or flatulence persists. Magnesia and sodium bicarbonate have the disadvantage of causing a change in the reaction of the body fluids to the alkaline side—*alkalosis*—if given in overdosage, and they may also cause some reactionary increase in gastric secretion immediately after their ingestion. Aluminium hydroxide preparations (Aludrox, Lactalumina and others) and mag trisilicate do not affect the blood reaction at all, so may be given in almost unlimited doses if desired without any danger of alkalosis. Bismuth salts and alumin silicate (kaolin) may have some beneficial action by forming an insoluble coating to the surface of an open ulcer. None of these preparations given in ordinary dosage, however, appreciably depress gastric acidity for more than a very short time indeed after their administration. The usual dosage of mag trisilicate is $\frac{1}{2}$ to 1 drachm and that of alumin hydroxide preparations 5 or 10 per cent. solutions in doses of 1 to 3 teaspoonfuls. The latter tends to be constipating and the former laxative so that a combination of the two together is often very satisfactory.

ANTISPASMODICS—During strict treatment full doses of atropine, hyoscyamine or belladonna are valuable in reducing gastric motility and spasm. Atropine sulphate gr $\frac{1}{10}$ is given in 60 minims of water before the 8 a.m. and 8 p.m. feeds, and a double dose may be given last thing at night. The dose should be increased by 10 minims every day up to the maximum the patient can take without unpleasant dryness of the mouth or paralysis of accommodation, as dosage short of this has no inhibitory effect at all on the stomach.

SEDATIVES—Both mental and physical rest are vitally important factors in the healing of an ulcer. To assist the former some sedative is advisable and phenobarbitone should be given in a dose of gr $\frac{1}{2}$ four times a day from the start of the treatment, unless it causes undue depression or any toxic symptoms. Bromides and chloral are unsuitable owing to their irritating action upon the stomach, and opium is not advisable owing to the danger of habit formation.

GASTRIC LAVAGE—An ulcer in the neighbourhood of the pylorus may give rise to obstruction owing to surrounding œdema and inflammatory swelling with pyloric spasm. In such cases continuous hypersecretion of gastric juice often occurs and the ulcer is unable to heal, so that a cicatricial obstruction is often suspected. If, however, the ulcer can be made to heal the "functional" obstruction may be relieved and any scarring produced may be insufficient to cause lasting obstruction. In such cases gastric lavage, either by stomach tube and funnel or by Senoran's evacuator, with complete removal of all gastric contents may be of great value. This should be done each night at 10 p.m., no feed having been given after 6 p.m. After the stomach has been emptied a full dose of alkali with a maximal dose of atropine is given, and as soon as not more than 3 or 4 oz. of fluid are found to be present on two consecutive nights the lavage may be discontinued.

After care —When healing is complete, usually at the end of 6 to 8 weeks, the patient must be advised regarding the prevention of recurrence. It is not difficult to cause an ulcer to heal, but the predisposing causes are still present, and the exciting causes may still be operative unless special precautions are taken to control them. It is essential to give instructions in writing for the patient to follow (*vide infra*). In addition help must be given him as far as possible as regards his mode of life, hours of work, domestic and family problems and any environmental factors which may produce anxiety, conflict or resentment. In hospital practice the Lady Almoner may often greatly help these patients, and elaborate dietary instructions are usually a waste of time.

From the beginning of treatment the swallowing of infective material should be kept in check as far as possible by careful dental hygiene, and as soon as the patient is convalescent thorough treatment of the teeth should be undertaken, and he should subsequently have his teeth put into good order at least twice a year. Any infective foci in the throat and nose should also be treated.

The patient should eat slowly and masticate thoroughly, he should acquire this habit during the period of observation and strict treatment. It should be impressed upon busy men that when they have no time to sit down to a proper meal it is better to drink milk or eat plain chocolate than to bolt some less digestible solid food. Tough meat, new bread and other articles of diet which cannot easily be chewed to a pulpy consistence should be prohibited. The patient should avoid the pips and skins of fruit, whether raw, cooked or in jam, cake or puddings, and pickles, salads and uncooked vegetables, such as celery, green vegetables are best given as purees with butter, but spinach, which is a powerful stimulant of gastric secretion, should be avoided. Condiments, vinegar, and unripe and acid fruit, high game, sausages and curry should be prohibited. The patient should be allowed to smoke only in strict moderation. He should remain on this regime until he has been free from symptoms for 2 years, and should follow it in a modified form for the rest of his life.

During periods of overwork and especially of mental stress, the patient should, if possible, spend 1 day or half a day a week resting and should be kept on a 2-hourly diet even in the absence of digestive symptoms. If he is much worried or sleeping badly he should be given gr $\frac{1}{4}$ to $\frac{1}{2}$ phenobarbitone three times a day and sufficient at night to secure sound sleep. Special care should be taken to avoid infections. If he gets a cold, sore throat, influenza or other infection, he should remain in bed on a very light diet until he has completely recovered.

The bowels should be kept regular with liquid paraffin. If this is insufficient, fluid preparations of magnesia may be given with it, but other aperients should be avoided. No strong tea or coffee should be allowed or any alcohol on an empty stomach. A little diluted whisky, light wine or beer may be permitted with meals for those who especially desire it.

The patient should for a time take a teaspoonful of magnesium trisilicate or aluminium hydroxide after meals and subsequently have some always available so as to be able to take enough to keep himself comfortable at the slightest suspicion of heartburn or gastric discomfort. He must be urged to carry an alkaline tablet always with him and suck one at any time if pain occurs and before this has had time to "get a grip". He should be warned of the danger of recurrence, and should be told to have a day or two off work on a strict diet at the first indication of a return of symptoms. If he does so this may be sufficient to ward off an attack, but if he waits until the symptoms become fully developed, a prolonged stay in bed is likely to be required.

The strict ulcer treatment and the post ulcer regime can be summarised as follows

Strict Ulcer Treatment

Stage 1

Every even hour whilst awake 5 oz. of milk. This can be warm or cold and may be flavoured with tea.

Every odd hour a 5-oz feed which may be made of any of the following

- (a) Arrowroot, Farola, Benger's, Horlicks, junket, custard These can be made more appetising by the addition of red currant, apple or other fruit jelly, and the junket may be flavoured with chocolate
- (b) At least two should consist of a thick soup or semi solid puree of potato, peas artichoke, cauliflower or parsnip

During the night the patient should have milk by his bedside, so that whenever he wakes he can take a feed

A rusk, plain biscuit or thin bread with butter or honey may be eaten with any of the feeds. A lightly boiled egg may be taken once or twice a day

Water may be drunk between feeds An ounce of strained orange, tomato or other fruit juice should be taken with three of the drinks and 100 mg of ascorbic acid dissolved in milk should be given daily

A teaspoonful of atropine mixture (atropine sulphate, gr $\frac{1}{100}$ in 1 dr water) is given before the last feed, and before two or three other feeds if the acidity is high The dose should be increased by 10 minims every day until an unpleasant degree of dryness of the mouth or paralysis of accommodation occurs the dose should then be reduced to that of the previous day

Half a teaspoonful of magnesium trisilicate in a little water with a teaspoonful of 10 per cent aluminium hydroxide may be given three or four times a day between feeds and last thing at night.

No smoking during the strict treatment

Stage II

2 hourly feeds

On waking	Milk or weak, milky tea.
Breakfast	Weak milky tea, or milk flavoured with coffee One egg—scrambled poached or soft boiled, or steamed finnan or white fish, or strained porridge cornflakes, groats or Demax with black currant puree, with milk and sugar Toast, or bread with butter or margarine Jelly marmalade, honey, syrup or jelly jam
Mid-morning	Milk flavoured with Marmite or Ovaltine Plain biscuit bread and butter, or Madeira cake
Midday	Steamed fish or chicken, rabbit, tripe or sweetbreads, liver, minced beef or mutton or tender beef or mutton Mashed or creamed potato Sieved vegetable or cauliflower tops Milk pudding baked custard milk jelly, junket or clear jelly with fruit puree or light plain sponge Or cream cheese butter cream crackers
2 p.m.	Milk flavoured if desired
Tea	Weak, milky tea. Bread butter or margarine Jelly, jam honey syrup or Marmite Plain biscuits Madeira or sponge cake
Evening Meal	Steamed fish etc. as at midday, or cheese custard cheese spaghetti cauliflower au gratin or cheese potato Bread butter or margarine Milk pudding etc., or ice cream or fruit puree, with milk and sugar
Bed time	Weak milky tea, if desired Milk flavoured as desired Bread and butter or plain biscuits

Night

Milk must be left at the bedside with an alkaline powder, but patients need not, as a rule, be wakened for regular feeds. If night pain occurs, however, he should be wakened at a time *before* this usually occurs and given a feed. If the pain is not prevented in this way, a continuous milk drip throughout the night is usually advisable (p 587)

*Post-Ulcer Regime
To be followed permanently*

1 A meal or feed (milk, plain biscuits or chocolate) should be taken at intervals of not more than 2½ hours from waking to retiring, and again if awake during the night

2 Eat slowly and chew very thoroughly. Adequate time should be allowed for meals, which must be punctual. Avoid taking a meal when tired, but rest for a short time beforehand if possible. When there is no time for a proper meal, it is better to drink some milk or eat some plain chocolate or biscuits than to bolt some less digestible solid food

3 Do not smoke on an empty stomach and not at all if you have any indigestion, it is best to avoid it altogether

4 During periods of overwork, and especially of mental stress, at least one clear day a week should be spent resting, on a strict 2 hourly diet, even in the absence of digestive symptoms. If you are much worried or sleeping badly, ask your doctor for a sedative

5 Special care should be taken to avoid chills. If you get a cold, sore throat, influenza or other infection, remain in bed on a very light diet until you have completely recovered

6 Avoid alcohol, except (if desired) a small quantity of beer, light wine or diluted whisky with (but never before) meals. Avoid pits and skins of fruit (raw, cooked or in jam) and raisins, currants, figs, ginger and lemon peel in puddings and cakes, nuts and unripe fruit

Avoid radishes, cucumber, raw celery, tomato skins, stringy French beans, hard peas and beans. Coarse green vegetables (cabbage, etc.) should be passed through a sieve

Avoid porridge made with coarse oatmeal and cereals and biscuits made with much coarse husk

Avoid tough or twice cooked meat, pork, strong meat soups and extracts and highly seasoned foods

Avoid most fried foods, especially if fried for a long time, avoid sausages and fried (chip) potatoes

Avoid mustard, pepper, vinegar, curry, pickles and chutney. If in doubt about any food, remember you must not eat anything which cannot be chewed into a mush

7 One or two tablets of magnesium trisilicate and aluminium hydroxide should be chewed twice a day between meals and also whenever the slightest indigestion or heartburn is felt. Noon and 4 to 6 p.m. are the times at which alkalis are most often required

8 Liquid paraffin or magnesia may be taken for the bowels if necessary, but no other aperient should be used without the doctor's advice

9 Visit your dentist regularly, every 6 months

10 Take no drugs in tablet form. Take no aspirin or Veganin but, if necessary, powdered calcium aspirin may be taken instead

11 If you have a return of symptoms go to bed on a strict diet at once. Consult your doctor and do not wait for the symptoms to get serious

Surgical Treatment

An operation should be advised under the following circumstances

- 1 At the earliest moment after a perforation
- 2 For pyloric obstruction without active ulceration
- 3 For pyloric obstruction with active ulceration if it persists after 3 weeks of strict treatment by rest and diet, with evacuation of the stomach every night
- 4 For a gastric ulcer causing organic hour glass contraction sufficiently severe to produce 3 hour stasis in the proximal segment This is very rare
- 5 When the symptoms recur after one or more courses of thorough medical treatment followed by adequate after treatment The number of such courses which may be tried depends upon such circumstances as the social position, occupation and place of residence of the patient Thus the better the social position of the patient, the less strenuous his occupation and the less important are occasional absences from business, and the warmer and more equable the climate, the less urgent is the necessity for operation The results of surgery are least satisfactory when evacuation is rapid, acidity is high, and the patient is young, and are best when the stomach empties slowly, acidity is normal or low, and the patient is over 50 Surgery on the whole becomes progressively more urgent in gastric ulcer the longer the condition has remained unhealed whatever the age of the patient, whilst in duodenal ulcer longer perseverance with medical treatment is usually advisable

6 *Hæmorrhage*—Surgery is very rarely advisable in young patients suffering from their first hæmatemesis Recurrent bleeding, however, from a proved chronic ulcer is usually best treated by operation, and in patients over 40 the need for this is greatly increased In most cases the acute hæmorrhage can be successfully treated medically (see p 570) and operation postponed till the patient is better able to stand it In others, however, in which bleeding appears to be continuing especially in older patients with sclerotic vessels, it is urgent to consider operation early as an emergency and not wait too long before asking for surgical help If operation is decided upon the patient must be given a blood transfusion in sufficient quantity to bring his hæmoglobin to 70 per cent, and dehydration and shock must be overcome by the use of adequate fluids and salt, given either orally or intravenously the blood urea and blood chlorides should be estimated before operation if facilities for these are available

At operation an attempt should be made to resect the ulcer, or if this is impossible to ligate the bleeding point failing this a series of sutures should be tied round the ulcer so as to cut off as much as possible of its blood supply Gastro jejunostomy alone is of course, quite useless unless pyloric obstruction is present

7 When for any reason it appears possible that a gastric ulcer is malignant and not benign (p 589) partial gastrectomy should be performed, even if naked eye appearance shows no evidence of malignancy

8 Though malignant degeneration of a simple gastric ulcer is rare, this change occurs more frequently in the pre pyloric than in the more commonly situated lesser curvature ulcers, and as it is often impossible with radiography to distinguish a simple ulcer from an early malignant ulcer in the prepyloric region partial gastrectomy should be performed in all cases of prepyloric ulcer which do not rapidly respond to medical treatment, gastro jejunostomy is not advisable as it is impossible to exclude early malignant changes even by inspection and palpation during the operation Ulcers on the greater curvature are most often malignant and these should be resected, the size of an ulcer is no safe guide as to its nature

Partial gastrectomy is the only satisfactory operation for a gastric ulcer wherever it is situated Gastro jejunostomy was previously thought to be the best operation for cases of duodenal ulcer with obstruction but at the present time most physicians agree in advising some form of gastro duodenal resection if the condition at operation

permits Technical difficulties, however, may be very great and if so the risk of the larger operation may not be justified as compared to that of simple short-circuit. If the gastric resection can be made high up and includes the pylorus the reduction in acidity is very considerable. In the case of gastric ulcer the results of gastrectomy are extremely good and the operative risk not high.

Complete achlorhydria only rarely results, and anastomotic ulcer may follow the operation in a small percentage of cases. The mortality of gastrectomy is higher than that of gastro-jejunostomy, but the risk of recurrence of symptoms following gastro-jejunostomy is not less than 30 to 40 per cent, whilst that following partial gastrectomy is certainly not greater than 10 to 15 per cent.

Post gastrectomy syndrome—After gastrectomy in some 10 to 20 per cent of patients attacks of great weakness, nausea and sweating may occur soon after eating, due probably to the rapid entry of food into the jejunum causing sudden distension. The symptoms are usually first noticed when the patient begins a normal life after the operation and are most likely to come on in the standing position. As a rule they disappear spontaneously within 1 or 2 years. They should be treated by giving dry solid meals with if possible, a rest lying down for a short time after eating, as there is often much distress concerning the symptoms and the patients are usually of the anxious type, a sedative is also advisable in treatment. In a few patients bouts of diarrhoea and steatorrhoea, with loss of weight, anaemia and signs of vitamin deficiency occur and in a small percentage of cases hypoglycaemic attacks 2 or 3 hours after eating have been shown to occur.

In spite of these occasional sequelæ, the results of partial gastrectomy are good, and patients should return after operation to a normal mode of life and diet, except for somewhat restricting the size of their meals and the rate at which they eat.

SUBSIDIARY METHODS OF TREATMENT—(a) *Continuous milk drip duodenal feeding*—The use of a Ryle's tube, with a continuous milk drip aimed at neutralising without intermission gastric acidity, is particularly useful in cases that are resistant to orthodox treatment. The tube is passed through the nose and retained for 2 or 3 weeks, often with very little discomfort to the patient. Additional solid feeds may be given by mouth as required.

(b) *Parenteral treatment*—Many attempts at ambulant treatment of peptic ulcer by injection treatment have been made, but it is unnecessary to mention these in detail. All act either by suggestion or through some mild non specific protein shock effect which perhaps aids slightly the healing of inflammatory processes in general. Gastric and duodenal extracts (entero gastrone) and histidine (an amino acid) are two preparations which have been widely advocated. Non specific injection treatment should never be given in place of thorough treatment on orthodox lines.

(c) *Vagotomy*—Section of both vagus nerves was originally suggested by Dragstedt and has been fairly extensively performed either through the thorax or the abdomen and, as mentioned previously, leads to reduction in quantity and acidity of the gastric juice, diminished motility of the stomach and possibly abolition of duodenal spasm. The operation is simple and safe, but its results have not confirmed its original hopes. It is now limited to patients who have developed jejunal ulcer after previous operations, or as a primary procedure only when combined with some short circuit operation or pyloroplasty to prevent subsequent gastric atony, stasis and vomiting.

POST-OPERATIVE GASTRO-JEJUNITIS AND ACUTE AND CHRONIC GASTRO-JEJUNAL AND JEJUNAL ULCER, GASTRO-COLIC FISTULA

Ætiology—The incidence of gastro jejunal ulcer and jejunal ulcer after gastric operations depends upon the acidity of the gastric contents following the operation. It is consequently much more common after gastro-jejunostomy performed for

duodenal ulcer, occurring in between 20 to 40 per cent. of cases, than when performed for gastric ulcer, and it never follows operations for carcinoma. It is very rare in women. It may occur after partial gastrectomy, especially when performed for duodenal ulcer or gastro-jejunal ulcer, as hyperchlorhydria persists in about 50 per cent. of cases. In 20 per cent. of cases the anastomotic ulcer develops immediately after the operation and in the majority within 2 years, though they may develop after as long as 20 years of freedom from symptoms.

The condition begins with inflammation of the anastomotic area—the neighbouring gastric mucous membrane and the first inch of the distal limb of jejunum. Acute ulcers, which may cause severe hæmorrhage or perforate, follow. These may heal spontaneously or develop into chronic ulcers. Gastro-jejunal and jejunal ulcers are of equal frequency.

Symptoms.—The indigestion which follows gastro-jejunostomy is due in a large proportion of cases to an anastomotic ulcer. The commonest symptom is pain, which comes on soon after meals in contrast with its comparatively late onset before the operation, and it is generally situated to the left of the umbilicus instead of at a higher level and in the middle line or to the right. It is usually less relieved by alkalis or food than is that of duodenal ulcer, and may radiate severely to the back and persist, particularly during the night. Hæmatemesis, which is sometimes the only symptom, occurs in about 50 per cent. of cases, and occult blood is usually present in the stools. Perforation may also occur without warning. In about 5 per cent. of cases the ulcer becomes adherent to the colon, and a gastro-colic, gastro-jejuno-colic or jejuno-colic fistula develops. This may at first cause little or no change in the symptoms, but sooner or later diarrhœa, which is occasionally fatty, and vomiting of feculent material or eructation of foul gas occur. In rare cases the proximal part of the colon becomes obstructed and severe pain and distension from accumulated feces results.

A "niche", corresponding with an ulcer crater, can generally be recognised by radiographic examination when a chronic ulcer is present, but in the frequent cases in which recurrent acute ulcers develop nothing abnormal can be seen. Gastroscopy has demonstrated the frequency of acute inflammation with or without erosions in the mucous membrane on the gastric side of the anastomosis in cases in which nothing abnormal is revealed with the radiograph, especially when hæmorrhage is the only symptom. Direct pressure over the stoma or the jejunum just beyond it often gives rise to pain. Free acid is invariably found after a fractional test-meal if care is taken not to allow the tube to pass through the stoma; in many cases there is hyperchlorhydria. An opaque meal can sometimes be seen to pass direct into the colon if a fistula has developed. In other cases the fistula can be recognised only after an opaque enema, when some of the barium is seen to pass direct from the colon into the stomach.

Treatment.—Prolonged treatment of exactly the same kind as that described for gastric and duodenal ulcer may lead to healing and the hypertrophic gastritis, which often occurs around the stoma in the absence of a chronic ulcer and which is a common cause of recurrent hæmorrhage, may also recover. Medical treatment, however, often fails and when the symptoms recur in spite of following a careful régime, the whole of the anastomotic area should be excised and a partial gastrectomy performed. It should be remembered that no sign of the ulcer may be visible on external examination, and that it is useless merely to divide any adhesions which may be found, as they are never responsible for the symptoms.

TUBERCULOSIS OF THE STOMACH

Tuberculosis of the stomach is very rare. In miliary tuberculosis the mucous membrane may be involved, but no symptoms are produced. In advanced pulmonary

tuberculosis a tuberculous ulcer may form, generally near the pylorus. The symptoms are indistinguishable from the dyspepsia common in such cases, unless hæmatemesis occurs, thus may, however, be due to the presence of a simple ulcer. Hurst recorded one case of chronic gastric ulcer and one of carcinoma, in which microscopical examination of the specimen removed at operation showed that secondary tuberculous infection had taken place. Both were associated with achlorhydria and had no distinctive symptoms, and the primary infection which was presumably present in the lungs was completely latent.

SYPHILIS OF THE STOMACH

Ætiology.—Syphilis of the stomach is apparently not uncommon in America and some Continental countries, but it is certainly very rare in England. It occurs in males twice as frequently as in females. Its incidence is greatest between the ages of 30 and 40, and it may develop any time between 4 and 40 years after infection.

Pathology.—Characteristic gummatous infiltration of the walls of the stomach, especially the pyloric end, has been found in specimens excised at operation and much less frequently at necropsy. In at least two post-mortem specimens spirochætes were discovered.

Symptoms.—Epigastric pain generally occurs immediately after meals, less frequently it is delayed as in ulcer. Fluids and small meals give some relief. Vomiting is common, but nausea, anorexia and anaemia are rare. The symptoms become steadily worse with increasing loss of weight and strength. Hæmorrhage is very rare, and occult blood is only occasionally found in the stools. Achlorhydria is present in 85 per cent of cases and hypochlorhydria in most of the remainder. The lesion is most frequently prepyloric, but pyloric incompetence owing to rigidity of the outlet of the stomach is as common as pyloric obstruction and less frequently an hour-glass contraction is present. A tumour is only occasionally palpable. In 25 per cent of cases other clinical signs of syphilis are found.

The radiograph generally reveals a local or diffuse involvement of the walls, which lead to stiffening, diminished mobility and abnormal peristalsis. The stomach is generally small. Less frequently there is a filling defect and very rarely a niche.

Diagnosis.—The possibility of syphilis should be considered when symptoms suggestive of cancer are present, even if there is no history or other evidence of syphilis. The Wassermann reaction should be tested. The diagnosis would be confirmed by the rapid improvement with anti-syphilitic treatment in spite of the failure of other measures.

Treatment.—The usual treatment for syphilis should be given, it is generally very successful. In late cases a short-circuiting operation may be required for pyloric obstruction caused by cicatricial contraction if anti-syphilitic treatment has failed to give relief.

CARCINOMA OF THE STOMACH

Ætiology and Pathogenesis.—Carcinoma of the stomach is the most frequent type of cancer found in the male sex, and is commonest between the ages of 45 and 65. When allowance is made for the number of people living at each age, however, it is seen that there is a steady rise in incidence throughout adult life. This incidence has increased during recent years and the ratio of men to women amongst people over 40 is approximately 3 to 1.

Hurst and others believed that carcinoma never developed in a normal stomach, and it is certainly true that evidence of chronic gastritis can be found pathologically in the neighbourhood of the growth in many cases. Chronic gastric irritation in

the form of repeated dietetic or other insults (see chronic gastritis) may perhaps be one factor in causation, but other susceptibilities are certainly also involved. Some positive hereditary history can be found in approximately 20 per cent of cases, but no occupation is especially involved. Clinical and post-mortem statistics show that the stomach accounts for only 30 per cent of deaths from carcinoma of the alimentary tract in England compared with 65 per cent in Holland and Sweden, and cancer of the stomach occurs in England with greater frequency in the poor than in the well-to-do, although the relative frequency of cancer in other organs is approximately the same in all countries and in all classes. The urban incidence is higher at all ages than the rural, but especially so in younger people.

In a proportion of cases cancer develops upon a chronic peptic ulcer—ulcer cancer. This happens much more frequently in the relatively rare prepyloric ulcer than in the common lesser curvature ulcer. In about 6 per cent of chronic ulcers excised by operation, which appear innocent to the naked eye, small areas are found in the margin which show microscopical evidence of malignant degeneration, and in about 16 per cent of cases of obvious carcinoma there is pathological or clinical evidence that the disease followed a simple chronic ulcer.

Carcinoma accounts for 99 per cent of all primary malignant growths of the stomach. Almost all arise from glands, and are adenomatous, but they may be of various types. The most frequent type is that of an irregular infiltrating ulcer with a hard raised edge, but soft fungating, polypoid or hard scirrhus (leather-bottle) growths also occur. The latter take the form of a diffuse rigid fibrous thickening of the stomach sometimes described as *linitis plastica*. As a rule carcinomatous ulcers are of large size when first diagnosed and any ulcer in the stomach with a diameter greater than 2.5 cm radiographically should raise the suspicion of a growth.

Symptoms.—When an individual above the age of 40, who has hitherto had a good digestion, suddenly begins to suffer from gastric symptoms, the possibility of cancer should always be considered, and with increasing age this possibility steadily increases. The nature of these symptoms depends partly upon the site of the stomach involved, but the most common one is epigastric discomfort or pain immediately or soon after meals. After a time the pain, which is generally dull and distressing, but not very acute becomes continuous, but it is still aggravated by meals. In a small proportion of cases the pain begins 2 or 3 hours after meals and is relieved by food, thus simulating duodenal ulcer, but there are never spontaneous remissions of symptoms, and in these cases achlorhydria is usually present. At an early stage the appetite diminishes, the patient having a special repugnance for meat. This is often the first symptom, though in ulcer-cancer the appetite may be maintained for some time. The anorexia may be associated with nausea, which can also occur independently, occasionally as the earliest symptom. In about one fifth of the cases there is a long history of symptoms suggestive of gastric ulcer, the pain having recently become more severe and continuous instead of intermittent.

Though anæmia is often present the blood picture may remain normal even in very extensive and inoperable growths with occult blood present in the stools. The anæmia is partly due to constant oozing from the ulcerated growth, but this has comparatively little effect unless actual hæmatemesis or melæna occurs, anæmia of this kind can be overcome by treatment with iron and, in severe cases, repeated transfusions. It is often of the simple achlorhydric type, which responds rapidly to treatment with large doses of iron, but occasionally it is Addisonian and responds to treatment with liver in spite of the presence of a growth. Flatulence is commonly present, the gas brought up being as a rule odourless but occasionally foul. Vomiting is generally present sooner or later. In cancer of the cardiac end of the stomach dysphagia with regurgitation of food immediately after swallowing occurs and the symptoms may be indistinguishable from those of a growth of the lower end of the œsophagus. Vomiting is commonly preceded by pain and nausea both of which it temporarily

relieves, but less completely than in gastric ulcer. The vomited matter contains blood more often than in gastric ulcer, it often has the appearance of "coffee grounds". Hæmatemesis is rare, but in exceptional cases may be the earliest symptom. In a large proportion of cases blood constantly oozes from the surface of the growth, so that one or more of the specimens obtained with a fractional test-meal may be obviously blood stained, and all are likely to contain occult blood. The oozing is unaffected by diet, so that occult blood is present in every stool examined, however carefully the patient is dieted. The growth sooner or later involves the pylorus in two thirds of all cases, the special symptoms then present are described under pyloric obstruction (p. 594).

The patient rapidly loses strength and weight, the emaciation being more than can be accounted for by the vomiting and diminished intake of food. In the late stages the disappearance of subcutaneous fat, loss of elasticity of the skin, œdema and anæmia give the patient a characteristic cachectic appearance. A low pyrexia is not uncommon and is almost constant if metastases are present in the liver.

In the earlier stages nothing abnormal is found on abdominal palpation, but sooner or later a hard, moderately tender tumour is generally felt. It is often most easily palpable when the stomach is empty, but occasionally only becomes obvious after meals. When the fundus or body is involved the tumour is felt descending from under the left costal margin, when it may sometimes be mistaken for an enlarged spleen. In carcinoma of the lesser curvature and pylorus the tumour lies across the upper part of the epigastrium.

Radiography often shows an irregular filling defect in the outline of the stomach which coincides with the tumour if one is palpable, and often involves the greater curvature. The normal progress of the peristaltic waves is interrupted, sometimes before any obvious deformity is present. The first radiological sign may be irregularity in the arrangement of the folds of mucous membrane seen in a radiograph taken after swallowing one or two mouthfuls of a suspension of barium sulphate. In carcinoma of the fundus the arc formed by the gas under the diaphragm is irregular in shape and reduced in size, and the growth itself may be faintly visible through the gas bubble.

If there is the slightest reason to suspect cancer a fractional test meal should be given. The resting juice often contains pus cells in excess of the leucocytes present in a specimen of saliva obtained at the same time and even if the specimen is not obviously blood stained red corpuscles are often found on microscopical examination. In 60 per cent of cases complete achlorhydria is present, and in at least another 20 per cent there is hypochlorhydria, in most cases secondary to ulcer free acid is present, sometimes actually in excess. If pyloric obstruction and achlorhydria are present, but not otherwise the resting juice generally contains lactic acid. It is however, absent if the stomach is washed out thoroughly the previous evening. It is thus a product of the decomposition of stagnating food and is not a secretion of the growth. Moreover the lactic acid is the inactive variety, and therefore of fermentative and not animal origin. It may also be present in other conditions such as migraine, if achlorhydria and gastric stasis are present together. Occasionally it is possible to detect fragments of tumour tissue in the test meal sediment.

Secondary deposits frequently occur in the liver and in 5 per cent of cases in both ovaries (Krukenberg's tumour) and the symptoms they give rise to may be the most prominent clinical manifestation. Direct spread to the peritoneum and omentum is common and irregular abdominal masses are often palpable, ascites may occur as a result of the malignant peritonitis and jaundice as a result of deposits in the liver or portal fissure causing biliary obstruction. A small gland just beneath the insertion of the left sterno mastoid muscle is generally attacked before any other cervical glands and less frequently deposits occur in the inguinal glands. The growth may spread along the urachus to involve the umbilicus, where a hard nodular mass

can be felt. A rectal examination should always be made, as a deposit is not infrequently present in the recto-vesical or recto-vaginal pouch at a comparatively early stage.

Perforation may occur, general peritonitis being usually prevented by the presence of old adhesions, so that a local abscess forms; less frequently the colon becomes involved and a gastro-colic fistula results, the patient then rapidly dying from emaciation due to constant faecal vomiting and severe diarrhoea.

Other terminal complications are suppurative gastritis, pylephlebitis, suppurative parotitis, thrombo-phlebitis migrans, septic pneumonia, empyema and infective endocarditis.

Diagnosis.—Apart from the history and the discovery of a tumour, radiological examination is the most important means of distinguishing a growth from other gastric disorders, the most characteristic signs being rigidity and irregularity of the mucosa, an intragastric filling defect, or a definite ulcer crater. The latter may be difficult to distinguish from a benign ulcer, but is often larger, more ragged and irregular and is usually antral or prepyloric. Ulcers on the greater curvature are usually malignant. The leather-bottle stomach is narrow, rigid and tube-like, and shows no peristaltic movements. In gastric ulcer the pain begins only at an interval after meals, and if present when food is taken it is temporarily relieved, whereas in cancer the pain generally begins directly after meals and is rarely relieved by food. In the group of cases in which duodenal ulcer is simulated, the absence of periods of freedom from symptoms, the presence of achlorhydria and the radiogram appearance should prevent a mistake in diagnosis. Pernicious anaemia may closely simulate a growth of the stomach; the megalocytosis and high colour index are characteristic of the former, and the presence of occult blood in the stools is distinctive of the latter. It should, however, be remembered that in rare cases pernicious anaemia may be associated with carcinoma of the stomach. Gastroscopy is, as a rule, only indicated when radiography is indefinite, but may be of great value in demonstrating the nature of an ulcer, whose edges may show the raised nodular indurated appearance characteristic of carcinomatous infiltration. It is especially indicated in any case of gastric ulcer which fails to respond satisfactorily under medical treatment. In late cases the diagnosis may have to be made from cirrhosis of the liver, with ascites, from heart failure, or from growths in the pancreas or colon with secondary deposits in the peritoneum.

Prognosis.—The average duration of life after the appearance of the first symptom is a year. Temporary improvement and considerable gain in weight may occur as a result of rest and careful dieting. Death is most frequently due to exhaustion; in other cases it results from one of the complications already mentioned. The results of surgery are disappointing, and the operation mortality of total gastrectomy is at least 25 per cent.; some guide to prognosis can be obtained if the tumour after resection can be graded for malignancy by the pathologist. If the patient is still alive 5 years after operation, his expectation of life is then the same as for the normal individual. Of those cases in which resection is possible at operation, not more than 15 to 20 per cent. are likely to be alive after 5 years, but only about one-quarter of all cases are resectable when first diagnosed. The prognosis is better in older patients, whilst in cases occurring in men under 30 it is almost hopeless.

Treatment.—Medical treatment is only palliative. In some cases the post-ulcer régime with alkalis may keep the patient comfortable, and small semi-fluid feeds are often all that can be tolerated. Gastric lavage may give relief, and an acid mixture may sometimes help to improve appetite. A sedative mixture or aspirin powders are generally sufficient to control pain for a time, but if morphine is required there should be no hesitation in giving as large a dose as is needed.

An operation should be performed in all cases in which there is no evidence of secondary deposits or involvement of glands beyond those in the immediate neigh-

bourhood of the stomach, unless it is found impossible to improve the patient's condition sufficiently to hold out any hope of success. If anemia is present it should be treated before operation with large doses of iron and, if necessary, blood transfusion until the hæmoglobin percentage is 80. When the pylorus is obstructed, the stomach should be washed out every morning and evening for a week before operation and large quantities of saline solution given by rectum. With proper preparation and bold and skilful surgery many apparently inoperable tumours can be completely removed. If secondary deposits make a radical operation impossible in a case of pyloric carcinoma, much relief may follow gastro jejunostomy. Small nodules in the liver are not a contraindication to partial gastrectomy, as they may grow so slowly that the patient remains quite comfortable for many months after the operation. Total gastrectomy combined with an œsophago jejunostomy has a mortality of 20 to 30 per cent, but may give remarkably successful results in suitable cases.

HOURL-GLASS STOMACH

A gastric ulcer situated on the lesser curvature may give rise to spasm of the corresponding segment of circular muscle fibres, which leads to a depression or "incisura" on the greater curvature, like a finger pointing at the "niche" on the lesser curvature. The degree of spasm varies with the activity of the ulcer, but a slight spasm may persist after healing is complete. It never gives rise to sufficient obstruction to cause stasis or increased peristalsis in the proximal segment. It may disappear on vigorous massage or after strongly contracting the abdominal muscles and sometimes, but not always, after the administration of atropine. A less persistent spasm may occur as a reflex result of duodenal ulcer, disease of the gall bladder and appendicitis.

Cicatrization of a very chronic gastric ulcer may produce an hour glass constriction. This hardly ever occurs in men, the large majority of cases being in women with such a high threshold of sensibility to pain that, though they may have had an ulcer for 20 or 30 years, they have never complained of indigestion of sufficient severity to raise a suspicion of the presence of organic disease. The frequency of hour glass stomach has steadily diminished during the last 25 years and the condition is now rare, probably owing to earlier diagnosis and better medical treatment. In 50 per cent of cases found post mortem the ulcer has healed completely and is replaced by a scar. The comparatively rapid healing of a lesser curvature ulcer by medical treatment, however large the ulcer may be, never results in an hour glass stomach; a period of many years with alternating periods of activity and spontaneous healing being essential for its development. The obstruction caused by an hour-glass contraction with a still active ulcer is always exaggerated by the presence of spasm so that the narrowing found at operation is often much less than would be suspected from the radiograph.

One of the two hour glass stomachs Hurst records in men was caused by a band passing from an ulcer on the lesser curvature to the omentum, the constriction disappearing when this was divided. Hour glass constrictions caused by cancer and syphilis are extremely rare.

Symptoms.—In organic hour glass stomach a history of comparatively slight indigestion occurring intermittently for many years, possibly with one or more hæmorrhages can almost always be obtained. The symptoms are similar to those of pyloric obstruction due to ulcer, with the exception that the amount vomited is generally less, and greater relief is obtained on lying down. There is no visible peristalsis unless the proximal segment is unusually large. The diagnosis is impossible without radiographic examination. In contrast with the hour glass constriction caused by spasm the neck passes from a point above and to the right of the lowest

part of the proximal segment. If an active ulcer is present, the niche produced by the crater is seen on the lesser curvature.

Treatment.—If no niche is present and the upper sac of the stomach is empty within 4 hours, the patient often keeps perfectly well by following the "post-ulcer régime" (p. 585). If the ulcer is still active, surgery is indicated. When the constriction is sufficiently narrow to produce definite stasis in the proximal sac, a gastro-gastrostomy should be performed, or if this is impossible and there is little or no stasis in the proximal sac, a partial gastrectomy. As an hour-glass constriction is occasionally associated with pyloric obstruction, the condition of the pylorus should always be investigated in case a gastro-jejunostomy is required in addition to a gastro-gastrostomy.

PYLORIC OBSTRUCTION

Ætiology.—Pyloric obstruction may be organic and incurable medically or functional and curable. Organic obstruction of the pylorus or duodenal bulb is caused by the contraction of fibrous tissue formed during cicatrization of an ulcer in its neighbourhood, 85 per cent. being duodenal and 15 per cent. prepyloric. Two-thirds of all cases of carcinoma of the stomach involve the pylorus. Pyloric obstruction is said to result from chronic gastritis as a result of hypertrophy of the mucosa or generalised sclerosis of the mucosa, submucosa and muscular coats. Syphilis is a very rare cause of pyloric obstruction. In infants, obstruction may result from hypertrophy of the pyloric sphincter (p. 596).

External pressure very rarely causes pyloric obstruction, and simple adhesions between the pylorus and the neighbouring viscera do not, as a rule, interfere with the passage of food into the duodenum. In exceptional cases, however, cholecystitis may lead to such strong and extensive adhesions with the pylorus that a certain amount of obstruction results. Gastropexia never causes pyloric obstruction (see Visceroptosis, p. 710).

The œdema and congestion round an active duodenal or prepyloric ulcer may cause severe obstruction, which disappears when the ulcer heals as a result of treatment. In such cases the obstruction is exaggerated by the presence of spasm of the sphincter, which may also occur reflexly with an ulcer on the lesser curvature and with cholecystitis. In rare cases a benign pyloric hypertrophy occurs in adults and causes delayed gastric emptying (see below).

Symptoms.—In the early stages attacks of severe pain may occur at varying intervals after meals owing to the violent peristalsis of the stomach in its attempt to overcome the obstruction. Later, nothing more than an unpleasant sense of fullness is experienced, especially after meals, but if frequent vomiting prevents the stomach from becoming much distended, attacks of pain are likely to persist. With an ordinary diet vomiting occurs regularly every day, but this characteristic symptom is less marked if the patient takes food which leaves little or no solid residue. The vomiting generally occurs at first in the afternoon or evening; but in the later stages, when dilatation has supervened, large quantities are vomited several times a day and often during the night. Articles of food may be brought up which have been eaten many hours or even days before. The odour is sour in non-malignant and foul in malignant cases. Excessive fermentation and putrefaction may give rise to offensive eructation, and in rare cases this is the first symptom noticed by the patient, especially, but not exclusively, in malignant obstruction. Wasting is progressive, and the tissues become abnormally dry and inelastic. The patient has generally little appetite, but complains of great thirst. The urine is scanty, and obstinate constipation occurs.

Pyloric obstruction occasionally gives rise to tetany and to symptoms simulating uræmia, but although there is a considerable rise in the blood urea the condition is caused by chloride deficiency and alkalosis and not renal insufficiency.

In addition to the symptoms already enumerated, others depending upon the cause of the obstruction, such as ulcer or carcinoma, are, of course, also present.

Pyloric obstruction leads to distension of the stomach. The signs of this, together with the distinctions between the malignant and non-malignant cases, are considered in the section on the examination of the stomach.

Prognosis and Treatment.—The treatment of organic pyloric obstruction is surgical. It is useless to waste time in well-marked cases with prolonged lavage or other medical treatment, as the improvement which follows operation is rapid and progressive. The immediate mortality is, however, high unless operation is preceded by preliminary medical treatment, which is essential in all cases to overcome dehydration and alkalosis. The stomach should be completely emptied every night and small quantities of custard, junket, vegetable purées and other soft, easily digestible foods with as much salt as possible, but very little fluid, given during the day. As much fluid as possible should be given per rectum, at least 3 to 4 pints of saline being run in either by a drip or as a 15 to 20 oz injection every 6 hours. The blood urea must be estimated and intravenous fluids given if this is high, the urinary chlorides or, if possible, the plasma chlorides should also be estimated and if below the normal level of 560 mg per cent, normal or half-normal saline should be given in amounts depending upon the degree of deficiency. The blood protein level may be low from prolonged starvation and vomiting, and a transfusion of plasma is an important help if this is the case. In severe cases potassium deficiency may follow the continued vomiting and is suggested by nodular severe prostration, low blood pressure and changes in the electrocardiograph tracing. Operation must be postponed until dehydration is overcome, the electrolyte balance restored and the urine output and intake are balanced.

When the obstruction is only partial and an active ulcer is present, the effect of medical treatment of the ulcer should be tried, as the obstruction may be largely due to the surrounding inflammation, which disappears when the ulcer heals, and when healing is rapid the scar generally gives rise to no obstruction.

BENIGN HYPERTROPHY OF THE PYLORUS

Ætiology and Pathogenesis.—Pyloric hypertrophy in adults is rarely congenital. In most cases it is associated with recurrent gastric ulceration, but in some it appears to follow prolonged nervous dyspepsia. In a few cases it is associated with chronic cholecystitis or appendicitis. The pyloric muscle is thickened and the pyloric canal elongated but not rigid.

Symptoms.—The symptoms resemble those of duodenal ulcer but are usually more closely related to anxiety or excitement than to eating. Pain is not so severe as in ulcer and may be quite absent. The main symptom is vomiting, which is often periodic and may date from childhood. Nausea is marked. The diagnosis can only be made radiographically, when the narrowed and elongated pyloric canal can be seen, no fixed ulcer deformity may be demonstrable, but this does not always mean that an ulcer is not present. Some gastric dilatation may result. The condition must be distinguished from malignant hypertrophy of the pylorus, which is due to an infiltrating carcinoma of the pyloric antrum and which converts the pylorus into a narrow inflexible tube through which no peristaltic waves can be seen to pass.

Treatment.—Treatment as for ulcer should be advised, with sedatives such as Amytal, gr $\frac{1}{2}$ t d s, but if there is any doubt as to the benign nature of the condition, laparotomy must be advised without delay. At operation a partial gastrectomy is usually advisable as the results of gastro-enterostomy are less successful and the exact nature of the condition cannot always be determined with certainty by sight and feel at the operation.

THOMAS HUNT

CONGENITAL HYPERTROPHY OF THE PYLORUS

Synonym.—Hypertrophic Pyloric Stenosis.

Definition.—This is a disease of early life, formerly believed to be a rarity, but now recognised as of not uncommon occurrence. It consists essentially in a great thickening of the pylorus, leading to gastric stasis, with all the symptoms that result from such a condition.

Ætiology.—The pathogeny of the disease is still obscure. The theory that it is simply a congenital malformation is not in harmony with the clinical facts, and the most generally accepted view is that it results from an overaction of the pyloric sphincter, the consequence of a lack of co-ordination between the gastric and pyloric mechanisms. There is some reason to suppose that the Anglo-Saxon and Teutonic races are more affected by the disease than the Latin, but it is exceptional to get a history of other cases having occurred in the family. Boys are affected at least four times as often as girls, and in a remarkably high proportion the patient is the first child of the family.

Pathology.—The most striking change is an immense thickening of the pylorus, due to overgrowth of its circular muscle-fibres. The stomach is dilated, its muscular coat somewhat hypertrophied, and the mucous membrane in a state of catarrh. The other post-mortem appearances are those usually met with in inanition.

Symptoms.—The child has usually been born at full term, after a natural labour, and in the majority of cases has been breast fed. For a week or two or longer all goes well, and then vomiting sets in. The vomiting is "projectile" in character, the stomach contents being violently shot out. The vomit is usually larger in quantity than the last meal, and is often mixed with mucus; the presence of any blood in it is very rare. Meanwhile the child steadily loses weight, but does not look really ill, and maintains his strength and activity. The bowels are obstinately constipated, and the motions small and dark.

The most important diagnostic sign of the disease is the palpation of the *pyloric "tumour"*. With experience many believe that this is always possible although not necessarily at the first attempt. The stomach should be empty, washed out with normal saline if necessary. The examiner sits comfortably at the left side of the baby and with a warm left hand palpates the right upper abdomen. The index finger should be on the liver edge and the next finger dips around the rectus towards the vertebral column. A feed is started and usually the pylorus is found as a round tumour, described as like the end of the nose felt through a blanket. It tends to harden and soften as waves of peristalsis reach it. As the stomach fills with the feed *visible gastric peristalsis* appears. On inspection of the abdomen, waves of contraction can be seen sweeping across its upper part from left to right. Sometimes three such waves can be seen at once, each being about the size of a golf ball. If they are sluggish in appearing a little gentle stimulation below the left costal margin will often succeed in eliciting them.

Complications and Sequelæ.—The complication most to be dreaded is the supervention of an infective diarrhœa, which in these cases is apt to prove fatal. Some degree of biochemical disturbance is also apt to develop in severe cases. There are no sequelæ of the disease; if recovery takes place, it is complete and permanent, and, indeed, many of the patients ultimately attain a degree of health and development beyond the average. The hypertrophy of the pylorus disappears.

Course.—The course of the disease varies greatly in different cases, and depends also to a large extent upon the treatment adopted, but unless operation is resorted to, it is always prolonged and recovery gradual. Even when the vomiting ceases, the weight may for long fail to rise, and the child may remain in a state of inanition, during which intercurrent disease may easily supervene.

Diagnosis.—This should not be difficult, provided the existence of the disease

is remembered. The vomiting is distinguished from that of indigestion by its projectile character, and the co-existence of constipation is characteristic. Palpation of the thickened pylorus is diagnostic. Visible peristalsis is suggestive but may be present in a wasted infant without true stenosis. Mild cases of pyloric spasm may simulate true stenosis, but in these the symptoms are less severe, and waves of peristalsis are indefinite. The patient is often a girl. Stenosis of the duodenum from congenital malformation may simulate pyloric stenosis, but the symptoms in the duodenal cases date from birth, and bile is present in the vomited matter. A radiographic examination sometimes helps in the diagnosis.

Prognosis—It is very difficult to estimate the chances of recovery or the relative merits of different forms of treatment statistically. Much depends upon the severity of the particular case, but in general it may be stated that no case is so severe that recovery is impossible. Cases treated in private do much better than those seen in hospital.

Treatment—There are two methods of treatment—medical and surgical. Medical treatment consists in washing out the stomach once or twice daily with normal saline, and carefully regulating the feeding. If breast milk is not available, a half cream dried milk with the addition of dextrimaltose is the best substitute, and should be given in quantities of 1 or 2 oz. every 2 or 3 hours, depending upon the degree of vomiting. Atropine methyl nitrate (*Eumydrin*) (1 to 5 ml. of a freshly prepared 1 in 10,000 solution or by a lamella placed under the tongue) is the best anti-spasmodic. If under this treatment the vomiting ceases, and the weight begins to rise, good and well. If not, or if the symptoms have set in early and with great severity, operation should be had recourse to, Rammstedt's plan of splitting the pylorus longitudinally being the procedure to be preferred.

ALAN MONCRIEFF

ACUTE DILATATION OF THE STOMACH

Ætiology.—After operations, especially for acute abdominal conditions, and much less frequently in the course of acute infections, especially pneumonia, the stomach suddenly becomes greatly dilated owing to a complete loss of tone. The dilatation, which is often much aggravated by severe aerophagy, leads to obstruction of the duodenum by the mesentery at the point where the latter crosses it, and the dilatation then becomes extreme.

Symptoms—The abdomen is very distended, large quantities of dark but not faecal fluid are vomited but the stomach is never completely emptied. The patient rapidly becomes very collapsed. "Black vomiting" after operations is almost always due to acute dilatation of the stomach, and not to the intestinal paralysis with which it is often associated.

Treatment—The stomach should be kept empty by aspirating through a Ryle's tube kept continuously in position, however ill the patient may be. Nothing should be given by the mouth, but saline solution should be injected continuously by intravenous drip to replace the fluids withdrawn. If recovery does not occur in 3 or 4 days, a jejunostomy should be performed, the patient being fed through the stoma till the stomach contracts to its normal size.

DUODENAL ILEUS

Ætiology—Minor degrees of duodenal obstruction are not infrequent and may be due to a number of causes. In some cases a congenital or an inflammatory band constricts the duodenum which then becomes hypertrophied and dilated above the

constriction, causing stasis of its contents and later atonic distension. In others the third part of the duodenum becomes occluded by the root of the mesentery carrying the superior mesenteric artery, which compresses it between this and the vertebral column. Such obstruction is usually intermittent, but may become continuous and almost complete in which case an extreme degree of mega-duodenum may result. Where the obstruction is due to an inflammatory band this usually results from a healing ulcer and is dense and thick, in contrast to congenital bands which are thin and translucent.

Symptoms.—The symptoms of duodenal ileus may closely resemble those of pyloric stenosis. In severe cases vomiting and pain may be violent, but more usually there is an irregular complaint of central epigastric fullness with feelings of distension and nausea, and increased discomfort 1 to 2 hours after eating. There is often relief of symptoms after vomiting and a striking and characteristic feature is the relationship of the symptoms to position. Patients often discover for themselves that they are more comfortable lying on their face with slight pressure on the abdomen, or in the knee chest position, and frequently resort to this position to obtain relief. In some cases attacks similar to migraine occur, in which severe headache, nausea and vomiting occur with an abrupt and complete cessation as if something had been released in the abdomen as soon as the vomiting ends. Most patients are worse if they have much standing to do and in a number the symptoms first arise after a period of worry or anxiety in which loss of weight has occurred. For this reason they are often thought to have an emotional origin and to be hysterical in nature.

Diagnosis.—Duodenal ileus must be diagnosed from duodenal ulcer, pyloric stenosis, migraine and from nervous dyspepsia. There are rarely any abnormal signs to be found, but there is sometimes a pendulous abdomen and evidence of recent loss of weight. A barium meal examination must be carried out in the erect position when a dilated duodenum may be seen with an obvious constriction, but this is not always demonstrable, as the condition is intermittent and radiographic examination may be quite normal. A duodenal ulcer is present in association with the ileus in some 20 per cent of cases.

Treatment.—In minor degrees of ileus reassurance as to its nature and the relief which patients feel when they are no longer regarded as "neurotic" may be all that is required. Advice as to position with raising of the foot of the bed at night and some light abdominal massage are useful, but abdominal belts or supports are of no value.

In diet small meals are advisable, but if the patient has lost weight it is important to try and regain this by a high calorie intake. When pain and vomiting are pronounced and radiographic examination shows definite duodenal enlargement, laparotomy is to be advised when adhesions may be severed or, if necessary, a duodeno-duodenostomy or duodenojejunostomy performed according to the exact conditions found.

DIVERTICULA OF STOMACH AND SMALL INTESTINE

Gastric diverticula are very rare. If present they are usually small and arise close to the oesophageal opening. In a few cases an acquired traction diverticulum may form as a result of adhesions following healing of a gastric ulcer, but other diverticula of the stomach are congenital, and no treatment is, as a rule, required.

Diverticula of the small intestine are found in between 1 and 2 out of every 1,000 necropsies. Except for the duodenum they almost all occur in the jejunum, where they are usually multiple, whereas duodenal diverticula are most often single. The majority are congenital in origin and consist of pouches on the free border of the intestine which are made up of all the intestinal layers, but in the duodenum they are more often acquired being found mainly in the second part as the result of a hernial protrusion through a weak spot in the muscularis mucosae. They occur especially

near the opening of the common bile duct and are often difficult to demonstrate either radiographically or at post mortem. They are most often found in women over the age of 50 and as a rule do not cause any symptoms. In rare cases perforation or hæmorrhage may occur, but more usually any symptoms produced are due to an associated duodenal ulcer. Indeed many cases reported radiographically as diverticula prove at operation to be large ulcer craters.

The symptoms of duodenal diverticula, if they occur, resemble those of duodenal ulcer, but it is important to exclude other causes carefully before attributing such symptoms to the diverticulum. This is most likely to be the case if the diverticulum is large, and if on radiographic examination it retains the barium after the duodenum is empty. It is uncommon for diverticula of the third part of the duodenum to cause symptoms.

Diagnosis is only possible by radiographic examination.

Treatment is surgical, if it can be shown that the diverticulum is causing symptoms of sufficient severity, but the operation may be a difficult one and removal a formidable undertaking.

THOMAS HUNT

DISEASES OF THE INTESTINES

INTRODUCTION

I THE FUNCTIONAL DIVISIONS OF THE INTESTINES

1 *The small intestines*—In the duodenum the food is mixed with the pancreatic juice, which is essential for the digestion of protein and fat, and with bile, which promotes the absorption of the products of fat digestion. In its passage through the small intestines the chyme is mixed with the succus entericus, which contains enterokinase, which activates the pancreatic ferments, and invertase, maltase and lactase. The chyme passes rapidly through the jejunum and most of the ileum, in the last 12 in. of which it remains for a considerable time. The terminal ileum indeed forms an "ileal stomach", in which the greater part of the digestion of protein, fat and carbohydrate takes place and the products of digestion are absorbed.

2 *The proximal colon*—Observations on patients with cæcal fistulæ show that about 500 g. of semi-fluid chyme, containing 90 per cent. of water with very small quantities of sugar, fat, salts, coagulable protein and of the soluble products of their digestion pass through the ileo-cæcal sphincter in a day. Water and all the soluble constituents of the chyme which reach the cæcum are absorbed there or in the ascending colon and proximal half of the transverse colon, which may therefore be regarded as the "colonic stomach".

3 *The distal colon*—The pelvic colon acts as a storehouse for fæces, to which they are conveyed through the transverse colon, the descending colon and the iliac colon when digestion in the colonic stomach is complete. Here they remain until the time for defæcation arrives.

4 *The rectum*—The rectum has the important function of maintaining the regular evacuation of fæces. It is empty except immediately before defæcation. The distension of its walls when fæces enter it produces the sensation which prompts the individual to perform the voluntary acts which help the efficient performance of the defæcation reflex.

II THE INTESTINAL MOVEMENTS

The movements of the intestines have two main objects (1) mixing the food with the digestive juices and bringing them into contact with the mucous membrane

which absorbs the products of digestion and water, and (2) propulsion of its contents from the duodenum to the rectum, and of the indigestible residue of the food from the rectum

1 *The small intestines*—In the small intestines peristalsis and segmentation take place simultaneously, the former with the object of propelling the chyme into the 'ileal stomach', and the latter with the object of mixing the food with the digestive juices and exposing it to as large an area of mucous membrane as possible. In the jejunum and greater part of the ileum peristalsis is the predominating motor activity, but when the ileal stomach is reached it ceases almost completely and segmentation becomes extremely active. After a varying interval peristalsis becomes active again, and as the ileo cæcal sphincter relaxes with the arrival of each peristaltic wave, the ileal stomach empties its contents into the cæcum.

2 *The colon*—When the colon is examined after an opaque meal it appears to be completely immobile. In spite of this, both segmentation and peristalsis occur under normal conditions, but their character differs considerably from the corresponding movements in the small intestine. Peristalsis occurs in the form of 'mass movements' about three times a day—a single very powerful peristaltic wave travels slowly along a considerable part or even the whole length of the colon, pushing in front of it most of the contents. Deep segmentation movements, which are too slow to be visible with the naked eye, can be recognised by comparing radiographs taken at 3 minute intervals and often in those taken at intervals of a single minute. Segmentation is the result of the ceaseless activity of the muscularis mucosæ, the normal 'hastration' of the colon seen in the radiogram being produced by projecting folds of mucous membrane. As a result of the continuous segmentation in the colon much of the water and all of the soluble constituents of the food and the products of their digestion which have escaped the small intestine are absorbed.

The chyme leaves the ileal stomach very slowly except during and immediately after meals, when, as a result of a gastro ileo cæcal reflex, frequent peristaltic waves pass down the terminal ileum to the ileo cæcal sphincter, which opens widely as each wave reaches it. The chief stimulus to mass peristalsis of the colon is a gastro colic reflex. On comparing these events it becomes clear that the ileal stomach passes its contents into the cæcum when it is necessary that it should be empty for the reception of the food coming down from the stomach after a meal, and that the colonic stomach similarly evacuates itself to leave room for the reception of the contents of the ileal stomach.

III DEFÆCATION

During defæcation the contents of the pelvic colon, together with any faeces which may be present in the descending and iliac colon, pass into the rectum. The distension of the rectum causes it to contract as a whole just like the bladder and at the same time causes reflex relaxation of the sphincter ani, so that the contents of the rectum are evacuated. Simultaneously the contents of the cæcum and ascending colon pass into the transverse colon, whilst the contents of the latter pass into the pelvic colon.

Normal defæcation depends upon a conditioned reflex. The infant is taught at an early age to empty his bowels directly he is placed on a chamber. The act quickly becomes a purely reflex one, and it continues to be so when he grows older and the chamber is replaced by the seat in the w.c. Breakfast by itself gives rise to a simple gastro colic reflex. Sitting down on the familiar seat in the w.c. is, however, the starting point of the more elaborate conditioned reflex, which produces the most efficient gastro colic reflex of the day, in which the whole colon from the cæcum to the rectum takes part. In the healthy adult defæcation remains to a great extent a conditioned reflex. It is enough to sit down in the accustomed place, perhaps with a pipe and a

newspaper, for the reflex to begin, often without the "call to defæcate"—the perineal sensation produced by the entry of feces into the rectum—and without the voluntary stimulus produced by the increased intra abdominal pressure caused by descent of the diaphragm and contraction of the abdominal muscles, these are, however, with the final contraction of the levator ani muscles, always brought into action to help in the complete expulsion of the feces

Failure to open the bowels on the first day of a holiday is not due, as is popularly supposed, to the "hard water" of the locality, deficient exercise in a train or on board ship, but to the unfamiliar w. c. and perhaps the unusual hour of getting up—or the absence of getting up—such small changes being enough to upset for the moment the delicately adjusted conditioned reflex

EXAMINATION OF THE INTESTINES

SIZE, SHAPE AND POSITION OF THE COLON

The cæcum and iliac colon are the only parts of the bowel which are always palpable under normal conditions. In very thin people and in patients with very lax abdominal muscles the whole colon except the splenic flexure and the pelvic colon can often be felt. Apart from these conditions the colon may become palpable when in a state of spasm or when filled with feces, and tumours involving it can often be recognised by abdominal examination. In all intestinal cases a rectal examination must be made, by this means not only the rectum but also part of the pelvic colon can be palpated. For further investigation of the size, shape and position of the whole colon in the erect as well as the horizontal posture a radiographic examination after a barium meal is essential. The pelvic, descending and iliac colon cannot always be seen satisfactorily, as they may be full only in the early morning, and defæcation empties them completely before it is convenient to make a radiographic examination

MOTOR FUNCTIONS

(a) PALPATION—In every case of intestinal disorder an abdominal and rectal examination should be made. No medicine or enema should be given during the preceding 24 hours. The quantity of feces present in each part of the colon varies greatly according to the time at which meals are taken and defæcation occurs. In a normal person whose bowels are satisfactorily opened after breakfast, the whole of the colon is empty during the greater part of the morning, though a thin layer of soft feces may cover the wall of the cæcum and perhaps the ascending colon and so render them partially opaque to the radiograph if a barium meal was taken 24 hours earlier, and a small quantity of semi solid feces may be present in the distal part of the transverse colon. Between 3 and 4 hours after breakfast the cæcum begins to fill, the filling becomes much more rapid after lunch, so that in a short time the ascending colon also becomes filled. During the rest of the day palpation shows the cæcum and ascending colon, and often the proximal part of the transverse colon, to be filled with soft feces, and the resonant note which is generally obtained on percussion over the right half of the colon in the morning is replaced by a dull note in the afternoon.

In the early morning the rectum is empty, but the pelvic colon can be felt through the anterior rectal wall to be filled with solid scybala, which sometimes extend upwards into the iliac and the descending colon. On getting up, but often only after breakfast, the pelvic colon empties some of its contents into the rectum, giving rise to the "call to defæcate". From this moment until defæcation has occurred is the

only time in which the rectum of most normal individuals is filled with faeces. At other times it is empty, and a proctoscope shows that there is not even a trace of faeces adherent to the mucous membrane. In defaecation the whole of the colon beyond the splenic flexure empties itself. Consequently the descending iliac and pelvic colon are empty during the whole morning, except that faeces may be conveyed during defaecation from the transverse colon into the lower part of the pelvic colon, and more may arrive from the proximal colon with the mass peristalsis occurring after lunch. Apart from this, the pelvic colon is generally empty or almost empty until after tea or more commonly after dinner, when another wave of mass peristalsis fills it with the contents of the colon from the neighbourhood of the hepatic flexure and the proximal half of the transverse colon.

If the rectum is full of faeces and the patient has no desire to defaecate, dyschezia can be diagnosed (see p. 605). If the faeces are soft it is clear that there can have been no delay in the passage to the rectum, such as is likely to have occurred if it contains hard and dry scybala. When the rectum is empty but the pelvic colon can be felt through the anterior rectal wall to contain scybala, the form of dyschezia which is due to inability of the pelvic colon to empty its contents into the rectum is present. In severe cases hard scybala may also be felt in the iliac and perhaps the descending colon.

(b) **THE CHARCOAL METHOD.**—By giving two or three charcoal lozenges with some food 8 hours after defaecation and observing after what interval black faeces are passed, the total time taken in their passage through the alimentary canal can be ascertained.

(c) **RADIOGRAPHIC EXAMINATION.**—1. *Opaque meal.*—The only reliable means of determining the rate of passage through the various parts of the alimentary canal is a series of examinations with the radiograph. If the bowels have not been spontaneously opened the morning before the opaque meal is to be taken, an enema should be given in the evening. It is important to discontinue the use of all aperients for at least 48 hours before the first examination, as the intestinal functions might otherwise be observed whilst still under their influence instead of under natural conditions. No aperients and no enemata should be used till the examination is finished, but the patient should make an attempt each morning to open his bowels naturally. If the attempt is successful, the stools should be examined to ascertain whether any of the barium has been evacuated. The patient should follow his usual occupations and take his ordinary diet. An examination should be made in the morning and evening of each day until all or most of the barium has been passed in the faeces or has reached the rectum. Normally a barium meal reaches the terminal ileum from $\frac{1}{2}$ to 5 hours after ingestion, whilst the rate of colon filling is extremely variable, barium continuing to enter the transverse colon intermittently for some 4 to 24 hours after it has first started to do so.

2. *Opaque enema.*—Although an opaque meal is the best means of obtaining information of the motor functions of the colon, an opaque enema generally gives earlier and more exact information concerning the possible presence, degree and position of a stricture, especially in the iliac and pelvic colon, which often cannot be satisfactorily examined by the former method. The patient lies on his back, and the barium sulphate suspension is run in from a container at a pressure of between 2 and 3 feet through a valveless Higginson's syringe connected with a rubber tube introduced just within the rectum, the syringe being used, when necessary, to help the passage of the fluid with light pressure. It often reaches the caecum in 2 minutes and almost invariably within 5 minutes. When the examination is complete, part can be run out through the tube, the rest being evacuated in the ordinary manner. A further radiograph is then made. Additional information, especially as to the presence of polypi, can often be obtained by injecting air into the colon after the greater part of the opaque enema has been evacuated.

An organic stricture of the colon generally obstructs the passage of the fluid, the shadow ending at the seat of the obstruction, which can be overcome only incompletely or not at all by waiting an additional 10 minutes, by increasing and decreasing the pressure of injection, by massage and by changes in posture. The flow of the enema is often prevented in cases of growth before there is any clinical evidence of obstruction such a hold up, with or without a marked filling defect in the colon may be present even when there is diarrhoea or the bowels still act normally and an opaque meal passes through the colon without delay. This is probably due to the occurrence of a spasmodic contraction of the bowel, which occurs at the seat of obstruction as soon as the enema reaches and distends the part immediately below it.

A barium enema may be the only way in which the presence of diverticulosis and diverticulitis may be detected, but it must not be forgotten that growths in the rectum low enough to be felt by the finger may not give any sign of their presence by radiography.

EXAMINATION OF FÆCES

The consistence, smell, colour and reaction of the stools when no aperient is being taken should be noted, abnormal acidity indicating excessive fermentation and abnormal alkalinity excessive putrefaction. The presence of mucus with solid stools is not in itself a sign of disease, but if it is mixed with blood or pus or present with fæces which are unformed though no aperient has been taken, some organic disease is almost certainly present. The presence of mucus with hard scybala or with soft stools obtained after the use of an aperient is due to the normal reaction of the colon to a mechanical and chemical irritant respectively, mucus being secreted in order to protect the mucous membrane. Red blood by itself may come from hæmorrhoids or a rectal polyp, if associated with mucus or pus or both, ulceration or cancer of the colon or rectum must be present. The brighter the colour of the blood the lower is its source. The presence of pus indicates disease of the pelvic colon or rectum unless the stools are very fluid. For the naked eye appearances of the stool in bacillary and amebic dysentery, see pp 114 and 276.

Microscopic examination may reveal the presence of blood corpuscles, pus, amebæ or their cysts and the ova of intestinal worms. The investigation of the stools for excess of food residue is described elsewhere (see p 612).

A bacteriological examination of the stools may show a relative excess of enterococci or *Bact coli*, the normal inhabitants of the colon, or strains of streptococci or *Bact coli* which are not normally present, or salmonella, dysentery or tubercle bacilli. If an endoscopic examination is made, a swab should be taken from the mucous membrane, together with any mucus or pus which may be seen, for cytological and bacteriological examination. In doubtful cases the agglutinating power of the patient's blood for abnormal bacteria isolated from the stools may be tested, and special culture media must be employed in the search for dysentery and other organisms.

OCCULT BLOOD

When blood is swallowed or is derived from an ulcer or growth in the œsophagus or stomach or an ulcer in the duodenum, it is evacuated in the stools partly as acid hæmatin and partly as hæmatoporphyrin. Both also appear in the stools when the blood originates in the colon unless diarrhoea is present, when the blood does not remain in the bowel long enough for the former to be converted into the latter. The chemical tests for "occult blood"—traces of blood insufficient to produce any change in the appearance of the fæces—depend upon the conversion of a substance with little or no colour, such as guaiac or benzidine, into a coloured substance when

oxidised by hydrogen peroxide in the presence of a carrier, such as hæmatin. The guaiac reaction is preferable to the benzidine, as, unlike the latter, it does not give a colour-reaction when iron salts are given by mouth, it can, therefore, be used in patients with ulcer who are receiving iron on account of post hæmorrhagic anæmia. Hæmatoporphyrin, which contains no iron gives neither reaction. A spectroscopic examination of the stools should also be made, as even considerable quantities of hæmatoporphyrin, which is occasionally present in the absence of acid hæmatin, would otherwise escape recognition. Moreover, a positive spectroscopic finding is valuable confirmation of a positive chemical reaction, as, although it is much less sensitive, there is less chance of error.

Before the stools are examined such foods as liver are excluded from the diet, but otherwise no special restrictions are required and green vegetables need not be excluded. For the guaiac test a small amount of fæces is macerated with glacial acetic acid into a thin paste. An equal quantity of ether is then added to extract the pigment and the ethereal extract is poured off, some being kept for the spectroscopic examination. Two or three drops of tincture of guaiac are added to the remainder, a small quantity of ozonic alcohol is then poured in, and a change of colour is looked for at the junction of the two fluids. A "positive" reaction is one in which a deep blue colour rapidly appears, a "feeble positive" reaction is one in which the colour is faint purple, bluish or greenish. If 1 ml. of blood enters the stomach or intestines, the next day's stool will give a positive reaction.

The benzidine test is carried out by adding some fæcal emulsion to a specially prepared powder containing 25 mg. of pure benzidine with 200 mg. of barium peroxide, when a positive result shows a green or deep blue colour developing at once or within 30 seconds.

A positive guaiac reaction signifies the presence of occult blood. A negative guaiac reaction proves its absence, except occasionally at the end of a period of hæmorrhage, when the spectroscopic test may alone be positive, as the traces of blood still present may then be completely converted into hæmatoporphyrin, which gives a characteristic spectrum, but does not give the chemical reaction.

By the spectroscopic test of the stools one can recognise (1) acid hæmatin, which also gives a positive guaiac and benzidine test, and (2) other hæmoglobin derivatives, i.e. porphyrins, which do not give a positive colour-reaction. The spectrum of acid hæmatin is so faint that it can be seen only in fairly concentrated solutions. The typical band of acid hæmatin (λ 620) is found only when considerable quantities of blood are present in the stools.

In the absence of hæmorrhoids and rectal or colonic polypi (which may be quite latent) and of bleeding from the mouth, throat and nose, the presence of occult blood in the stools is strong evidence that an ulcer or growth is present in the œsophagus, stomach or intestines. It is occasionally found in gastritis, diverticulitis and in such conditions as cirrhosis of the liver.

PROCTOSCOPIC AND SIGMOIDOSCOPIC EXAMINATION

Wherever there is any possibility of organic disease of the pelvic colon or rectum a proctoscope and, if necessary, a sigmoidoscope should be passed, after a preliminary digital examination. No special preparation is required but the patient must have had his bowels emptied as completely as possible shortly before the examination. No aperient or enema is necessary, but if the rectum is found to be full of fæces, the examination should be abandoned and repeated later 3 to 4 hours after a simple bicarbonate (1 per cent.) wash-out has been given. The instrument should be passed without an anæsthetic either in the knee-elbow (which is the easiest), or in the left lateral position if the patient is easily exhausted or elderly.

The passage of a proctoscope requires very little experience, and sigmoidoscopy is practically without discomfort or danger to the patient provided the examiner avoids using any force in passing the instrument and has had adequate instruction in the technique required.

Proctoscopy may show the presence of ulcerative colitis, in which the rectum is usually involved from the outset, and is the last part of the bowel to recover, it will also enable growths to be seen as far up as the pelvic rectal flexure. It is essential to pass a sigmoidoscope in any case of suspected malignant disease if nothing abnormal is seen proctoscopically, and in cases of amœbiasis the fuller examination is also anvisable. In these cases swabs may be taken direct from any ulcers seen, and scrapings made with a sharp spoon examined at once under the microscope, may show amœbæ when ordinary stool examinations have failed to do so. This is also true of rectal schistosomiasis in which the ova of the schistosoma may be only found from scrapings of the rectal ulcers, and without which diagnosis is impossible.

FUNCTIONAL DISORDERS OF THE INTESTINES

CONSTIPATION

Definition—Constipation may be defined as a condition in which no residue of the food taken during one day is excreted within the next 48 hours.

Ætiology and Pathology—Constipation may be due to (1) the passage through the colon being delayed, whilst defæcation is normal—colonic constipation, (2) the evacuation from the pelvic colon and rectum being inadequately performed, whilst the passage through the colon is normal—dyschezia, and (3) insufficient formation of fæces.

1 COLONIC CONSTIPATION—Delay in the passage of fæces through the intestines is due to their motor activity being deficient, or to the force required to overcome some obstruction being insufficient. The motor activity of the colon may be diminished owing to deficient reflex activity, inhibition or uncontrolled and irregular action. It is rarely if ever due to actual weakness of the muscular coat. The reflexes which maintain intestinal activity may be reduced owing to lack of mechanical and chemical stimulants in the food, or to some endocrine deficiency as in hypothyroidism. The inhibitory sympathetic nerves may be stimulated centrally by depressing emotions, and reflexly in painful diseases and injuries of any part of the body, but particularly of the abdominal and pelvic viscera.

Painful colon spasm may be induced reflexly by the presence of mild irritants in the colon of a patient with an abnormally excitable nervous system—spastic constipation. Such an irritant may be the abnormally hard and dry fæces which result from dyschezia, or from insufficient consumption of water, or its excessive loss in the urine or sweat, such as may occur in Europeans living in the tropics. Spasm may result from irritation by organic acids in intestinal carbohydrate dyspepsia, in which constipation may alternate with diarrhœa. Spastic constipation is a constant symptom of diverticulitis. The reflex may also be excited by disease in other parts of the abdomen, especially the gall bladder and appendix. Similar spasmodic contraction of the intestines occur as a result of excessive smoking and in lead poisoning.

The work to be done by the intestinal musculature is excessive when an organic obstruction such as stricture, adhesions or volvulus narrows or blocks the intestinal lumen.

2 DYSCHIEZIA—Dyschezia may be due to inefficiency of the defæcation reflex, to abnormally hard and bulky fæces requiring excessive force for their evacuation, or an obstacle to efficient defæcation, such as spasm or congenital or acquired strictures.

of the anal canal. Dyschezia due to inefficient defaecation is the most common cause of severe constipation. It often originates in neglect to respond to the call to defaecate owing to laziness, insanitary condition of the w.c. or false modesty. The conditioned reflex upon which defaecation normally depends is gradually lost. The rectum dilates so that an increasing quantity of faeces is needed to produce the adequate internal pressure required to give the sensation of fullness which is the natural call to defaecation. Finally the sensation is lost completely. But the patient is still capable of emptying his rectum if he tries. He has, however, by now often convinced himself that he cannot get his bowels to open unless he takes enemata or such enormous doses of aperients that the fluid faeces practically act as enemata. He suggests to himself that his rectum is powerless to act by itself, and soon the dyschezia becomes in part a psychological inhibition.

In many individuals the sensation of a full rectum is ignored because it does not occur at their usual time for defaecation, so that after a while a rectal tolerance is developed; in such patients it is important to instruct them to empty their bowel in accordance with their sensations rather than with the supposed rules of a once-a-day convention.

Dyschezia may be due to various other causes, such as weakness of the voluntary muscles of defaecation, the assumption of an unsuitable position during defaecation and voluntary inhibition from fear of pain in diseases of the anal canal, such as a fissure. But whatever the primary cause, the final result is the same. The conditioned defaecation reflex is lost, and the incomplete evacuation of the rectum results in the accumulation of faeces and consequent dilatation of the rectum.

Careful training is required from earliest infancy in order to develop the defaecation reflex, and neglect of this is the cause of the dyschezia of infants, in whom the slight additional distension produced by the introduction of a finger or a piece of soap into the rectum results in an adequate stimulus.

The rectal muscle-sense is abolished or defective in diseases of the spinal cord in which the defaecation centre itself or the fibres connecting it with the brain are involved.

3. The third great class of constipation is due to the quantity of faeces formed being insufficient to produce an adequate stimulus in the pelvic colon and rectum, and to a less extent in the rest of the colon. The insufficient bulk of faeces is due to an inadequate quantity of food residue reaching the colon as a result of anorexia, or of oesophageal or pyloric obstruction, or to unusually complete digestion and absorption of an abnormally low-residue diet.

Symptoms.—Many people regard themselves as ill if they do not have one action of the bowels a day, although this is really nothing more than a convenience, being found to suit the habits and diet of the majority of civilised people. Perfect health may be maintained by individuals who defaecate regularly two or three times a day, and by others who obtain an evacuation once in 2, 3 or more days. The latter, so long as defaecation, when it does occur, is complete, can no more be regarded as diseased than those otherwise normal people whose hearts beat only 40 or 50 times a minute. Many, however, although they may suffer no inconvenience for a considerable time, finally develop symptoms due to faecal accumulation, gradually increasing quantities of faeces being retained. For practical purposes, therefore, an individual may be considered constipated if his bowels are not opened at least once in every 48 hours. A less frequently recognised variety of constipation is that in which insufficient faeces are excreted, although the bowels may be opened every day, often more than once, a condition analogous to retention of urine with overflow.

It is important to distinguish the symptoms of constipation from those of the conditions which give rise to it. There is little evidence in support of the view that toxic absorption in constipation is a cause of the headache, fatigue, anorexia, furred tongue or mental symptoms which are so often attributed to it. The majority of

such symptoms are without doubt psychoneurotic and attributable largely to the anxiety caused by the supposed dangers of faulty bowel action. Some may be a direct reflex effect due to overloading and distension of the rectum, as is supported by their immediate disappearance after defaecation, and the fact that they may be experimentally simulated to some extent by filling the rectum with tow or distending it with a rubber balloon in normal individuals.

Fæcal retention is a common cause of intestinal flatulence and colic. In rare cases a fæcal tumour may form, generally in the pelvic colon, and give rise to obstruction. A fæcal accumulation in the rectum may cause hæmorrhoids, pruritus ani, catarrhal proctitis and neuralgic pains in the perineum, back and down the legs. Hard fæces make defaecation painful, and their passage may give rise to anal ulcers.

Diagnosis.—It is comparatively rare for a patient to consult a doctor on account of constipation without having already attempted to cure himself with aperients. But no accurate diagnosis can be made until it has been ascertained whether he is actually constipated at all. The symptoms generally ascribed to auto-intoxication caused by intestinal stasis are often really produced by purgatives, which lead to the excessive production of toxins by hastening the half-digested contents of the small intestine into the cæcum, where fermentation and putrefaction are consequently increased. Purgatives also cause the contents of the transverse, descending and pelvic colon to be fluid instead of solid, so that absorption of toxins continues throughout the whole length of the bowel instead of in the cæcum and ascending colon alone. In spite of his probable protests the patient is instructed to see what happens if no drugs are taken for 3 days, an effort being made to open the bowels each morning. In many cases he loses his abdominal pain and his so-called toxic symptoms. The bowels are often opened daily, in which case a diagnosis of hysterical pseudo-constipation can be made—hysterical because the patient had suggested to himself, as a result of faulty education aggravated by the reading of pernicious advertisements, that he was constipated and required aperients to keep himself well. In such cases explanation of the physiology of his bowels and the origin of his symptoms with persuasion to try and open his bowels regularly each morning without artificial help results in cure. In some cases, however, the patient does not succeed in opening his bowels, although he may feel more comfortable than when he was taking drugs. A second abdominal and rectal examination should then be made. If no sign of organic disease is present and the rectum is found to be filled with fæces, dyschezia can be diagnosed (*vide supra*).

In severe cases it is advisable to investigate the motor activity of the intestines radiographically, a barium meal being given after the patient has discontinued taking aperients. Great care must be taken, however, in interpreting the wide normal variations in the passage of barium in different individuals. Thus, ileal stasis should be diagnosed only if no trace of barium has reached the cæcum 6 hours after the opaque meal, or if a considerable quantity of barium-containing chyme is still in the end of the ileum 6 hours after evacuation of the stomach is complete. If most of the barium is still in the cæcum and ascending colon at the end of 24 hours, stasis is present, even if a little has passed to the more distal parts of the colon; but a faint shadow of the cæcum is often visible in normal individuals even 3 days after the meal. If the splenic flexure is reached in 24 hours, but barium is still in the colon at 72 hours, there must be stasis in this part of the bowel. In dyschezia most or all of the barium has accumulated in the rectum in 24 hours. In pelvic colon dyschezia a similar accumulation occurs in the pelvic colon, but the rectum remains empty.

Treatment.—Under no circumstances should the patient fail to make an effort to open his bowels after breakfast, even if he feels no desire to do so, and a call to defaecation felt at any other hour in the day should be obeyed at once. Sufficient time should be spent over the act of defaecation, and it is often advisable to pay two visits to the w.c. at short intervals, perhaps before and after breakfast. In order to

prevent the temptation to hurry over defæcation, the closet should be clean, devoid of smell and sufficiently warm in winter. In dyschezia with weak abdominal muscles a footstool, 9 in. lower than the seat, should be provided. In many cases of dyschezia no treatment is required beyond explaining to the patient the nature and cause of his condition and persuading him to give up aperients and to make an effort to empty his rectum, which he must realise is quite capable of doing its work. By perseverance it is very often possible to re-develop the lost conditioned reflex upon which normal defæcation depends.

It is most important to see that sufficient food is taken as constipation is often as much due to its insufficient quantity as to its unsuitable quality. The diet should contain an increased proportion of vegetable foods especially those which contain much cellulose and organic acids. Fresh or dried fruit should be taken three times a day, and green vegetables or salad should be eaten at lunch and dinner. Stewed prunes taken at breakfast are especially valuable. Porridge and cream and whole meal brown bread are also useful. Sufficient fluid should be drunk, a glass of water taken on rising in the morning often helps the bowels to act after breakfast.

The majority of cases of constipation can be cured without drugs if proper treatment is instituted at a sufficiently early stage. In dyschezia purgatives act only when fluid stools are produced, colic and toxic symptoms often resulting and a considerable quantity of fluid and nutritive material being wasted. In the treatment of diseases which are aggravated by coexisting constipation purgatives should be regularly given. They are also useful for making the stools soft when straining at stool is accompanied by danger, as in patients with heart disease. In colonic constipation, when advice and dietary treatment prove insufficient, purgatives must also be used, but an effort should be made to dispense with them at the earliest possible moment. The stool produced by an aperient should be normal in size and consistence, and the dose should be so regulated that one stool is passed every day. It should cause no pain or discomfort and should not irritate the intestinal mucous membrane sufficiently to lead to the appearance of mucus in the stools. An infusion of senna pods in cold water is particularly useful, as senna acts on the colon alone, and the dose can be regulated from day to day by the patient. An attempt should be made at intervals to reduce the number of pods by one at a time, until finally none may be required. Accurately standardised extracts of senna are also useful and simpler to regulate.

The bulk of the fæces may be increased by the administration of an unirritating vegetable mucilage such as Isogel or coreine derived from psyllium seeds which pass through the intestines without undergoing decomposition or absorption. These preparations are valuable when the fæces are hard and dry, and in dyschezia the soft stools which result from their use are expelled with less difficulty than ordinary fæces. From a teaspoonful to a tablespoonful of paraffin or double the dose of a plain 50 per cent. paraffin emulsion may be taken immediately after one, two or three meals every day, to act as an intestinal lubricant, or a teaspoonful of Isogel or coreine which absorbs water to form a bulky gelatinous mass which becomes intimately mixed with the fæces may be taken with one or more meals in addition to or as a substitute for paraffin. Half a tumblerful of water must be taken after each dose of Isogel otherwise it may cause severe pain in the chest or epigastrium.

The majority of cases of moderately severe constipation are more or less cumulative, excess of fæces being always present in the large intestines. It is therefore necessary that the colon should be completely evacuated before other methods of treatment are adopted. This can best be done by washing the colon out with 1½ or 2 pints of warm water run into it from a douche can or funnel at low pressure through a soft catheter inserted just beyond the anal canal. The regular use of enemata, Plombières douches and of continuous intestinal lavage with many pints of fluid are harmful both from a physical and psychological point of view.

It is essential in treating dyschezia to keep the rectum and pelvic colon empty, so that they may in time regain their normal tone and contractile power. This can be accomplished by the use of glycerin suppositories or of a 1 oz. enema consisting of equal parts of glycerin and water every morning, if a prolonged attempt to defæcate naturally has proved unsuccessful. The strength of the enemata should be gradually reduced by replacing a drachm of the glycerin by water every other day until only water is used. As a rule the normal defæcation reflex and with it the tone and contractile power of the rectum slowly return.

When dyschezia is due to inability of the pelvic colon to empty its contents into the rectum, 6 oz. of paraffin should be injected on going to bed and retained during the night, the bowels are then generally opened without difficulty in the morning. If, however, they fail to act, a plain water enema should be given.

When the sphincter ani is in a condition of spasm as a result of inflamed hæmorrhoids or an anal ulcer, or when the anal canal is congenitally too narrow or a stricture has followed an operation for hæmorrhoids, relief can be obtained by dilating the passage by means of diathermy applied locally through a conical electrode.

Regular exercise in the open air is a useful means of preventing constipation, especially in individuals who follow a sedentary occupation. When any of the voluntary muscles of defæcation are weak, considerable benefit can be gained by the performance of remedial exercises every morning and evening. Special attention should be devoted to the levator ani muscles, especially in women in whom the pelvic floor has been injured during parturition, and in cases in which there is any tendency to prolapse on straining at stool. Stasis in the proximal part of the colon may be benefited by massage applied directly to the affected part.

DIARRHŒA

Definition—Diarrhœa is a condition in which unformed stools are passed. Defæcation generally occurs several times in the day, but mere frequency of defæcation is not diarrhœa, for this may even be associated with constipation. The bulk of feces excreted in 24 hours is generally excessive, but this again may occur without diarrhœa, as excessive feces are occasionally formed when the passage through the alimentary canal is not abnormally rapid. The one essential factor in diarrhœa is the abnormally rapid passage of the food residue through the alimentary canal.

Ætiology—1. **EXCESSIVE STIMULATION OF MOTOR ACTIVITY**—The most common cause of diarrhœa is the presence in the food of excess of the mechanical and chemical stimulants of intestinal activity. Thus over indulgence in green vegetables, salads and especially unripe fruit is a familiar cause. Chemical irritants may also be swallowed in decomposing food, as in some cases of fish and meat poisoning, but food may also cause diarrhœa by giving rise to a bacterial infection of the intestine (see p. 119). Diarrhœa very frequently results from the habit of taking aperients, either in excess of what is required for the correction of chronic constipation, or even when the bowels left to themselves would act quite normally.

Chronic diarrhœa is a common sequel of the acute diarrhœa following infection with a pathogenic organism which gains access to the intestines in contaminated food or water, and it may follow acute general infections such as influenza. In some cases the infection is derived from a septic focus in the mouth, nose or pharynx, and in rare cases recurrent subacute appendicitis is the source of a chronic infection of the colon. Some infective bacteria, such as those of the *Salmonella* group, act chiefly on carbohydrates and may lead to excessive fermentation. Others, such as streptococci and various anaerobes, act on proteins and lead to putrefactive diarrhœa. Severe intestinal carbohydrate dyspepsia (p. 629) may give rise to chronic diarrhœa or

alternating constipation and diarrhoea, and deficient digestion of proteins, resulting from either gastric or pancreatic insufficiency, may lead to a non infective putrefactive diarrhoea. Deficient digestion of fat and deficient absorption of fatty acids and soaps give rise to fatty diarrhoea (steatorrhoea) (see p. 620).

Diarrhoea is sometimes gastric in origin. This *gastrogenous diarrhoea* may occur when the gastric juice is deficient or absent, or the stomach empties unduly rapidly. An abnormal number of organisms reaches the intestines in these circumstances, as the partial protection afforded by the bactericidal action of the hydrochloric acid in the stomach is lost. As in addition to the digestion of meat in the stomach the connective tissue of meat and the cellulose of vegetables are normally softened by the hydrochloric acid of the gastric juice, undigested lumps of meat and fragments of vegetable leave the stomach and pass through the small intestine to the colon, where they are liable to undergo bacterial decomposition. The irritation of the mucous membrane of the intestines by the insufficiently divided fragments of food and by the products of bacterial decomposition leads to diarrhoea, which may become aggravated by secondary enteritis or entero colitis if the irritation is sufficiently intense or prolonged. Similar gastrogenous diarrhoea may occur after the performance of a gastro-jejunostomy or partial gastrectomy, the food leaving the stomach with such rapidity that the intestines are overwhelmed with undigested and irritating food.

Lastly, stimulation of intestinal activity may occur in general diseases and cause diarrhoea such as is found in uræmia, hyperthyroidism and septicæmia.

2 OVER EXCITABILITY OF THE NEURO-MUSCULAR MECHANISM WHICH CONTROLS THE INTESTINAL MOVEMENTS.—(a) *Post-prandial diarrhoea*.—Under normal conditions the entry of food into the empty stomach gives rise to a gastro colic reflex, which is the chief stimulus to the movements of the colon. In most individuals this is followed by defæcation only after breakfast, as the pelvic colon is then full, and the sudden passage of feces from it into the rectum gives rise to the call to defæcation. Sometimes the gastro colic reflex is abnormally active. This may manifest itself after breakfast, a formed stool is passed first, but in the course of the next half-hour or hour one or more loose stools are passed in addition. In severer cases the bowels are also opened after dinner and less frequently after lunch, the stools again being often soft or fluid.

(b) *Nervous diarrhoea*.—It is not uncommon for a fright to result in the immediate passage of a semi fluid stool. In some patients, attacks of diarrhoea occur whenever they are in any place where it would be awkward for them to relieve themselves. When this has once happened, it is likely to recur under similar circumstances, largely owing to fear that it will do so. In such cases there are almost always other phobias and evidence of psychoneurosis. At the same time it must be remembered that diarrhoea, whatever the cause, tends to be worse after meals, especially breakfast, and is also frequently influenced by nervous factors, so that it is important to exclude any other primary causes before diagnosing a case as one of purely nervous diarrhoea. The diarrhoea, for instance, of such conditions as ulcerative colitis is markedly affected by the emotions, and many individuals who have lived in the tropics and suffered from repeated attacks of bacillary dysentery or from amebiasis often continue to be liable to diarrhoea for many years after their return to a temperate climate, a condition sometimes described as irritable bowel.

3 ORGANIC INTESTINAL DISEASE.—(a) *Enteritis*.—The profuse, watery diarrhoea of acute food poisoning and infections such as the enteric fevers is a result of acute enteritis, which is generally accompanied by acute gastritis, though the colon is often spared. The irritating products of the excessive bacterial activity resulting from the stasis in organic obstruction of the small intestine give rise to enteritis, consequently diarrhoea and not constipation is almost always present in chronic small intestine obstruction.

In these conditions the chyme from the stomach passes rapidly through the

small intestine and the bulky fluid contents are evacuated by the colon almost at once, even though this may remain quite healthy

(b) *Colitis* —Diarrhœa is a constant symptom of acute inflammation of the colon, except in the rare cases in which this is confined to the cæcum and ascending colon. Thus it is always present in ulcerative colitis and bacillary dysentery, in which the disease begins and remains longest in the pelvic colon and rectum, but it may be absent in some cases of chronic amœbic dysentery in which the cæcum is mainly involved. Diarrhœa may occur in carcinoma of the colon, especially the distal part, before the lumen has been narrowed sufficiently to lead to fæcal retention. The diarrhœa in these conditions is due to irritation of the bowel by the products of bacterial decomposition of the albuminous exudate of the diseased parts, and in colitis also to deficient absorption of fluid by the inflamed mucous membrane.

Symptoms —The chief and sometimes the only symptom of diarrhœa is the abnormally frequent passage of abnormal stools. In small intestine diarrhœa discomfort and colicky pain are often felt round the umbilicus. In severe cases of diarrhœa, whatever its origin, discomfort or pain is felt over the whole of the lower part of the abdomen for a short time before the bowels are opened. It may be followed by a sensation of soreness, but the abdomen is neither tender nor rigid, and warm applications generally relieve it. At times severe colic occurs, which may be temporarily relieved each time the bowels are opened or flatus is passed. The passage of a large and watery stool is often followed by a feeling of exhaustion and faintness, which may be accompanied by sweating and coldness of the extremities and occasion

constant presence of faeces in the rectum calls forth the secretion of clear mucus. In slight cases there may be nothing more than a thin layer of mucus over the hard lumps of faeces, in severer cases a larger quantity of fluid mucus, which is often stained brown, is passed either alone or with hard particles of faeces. In all such cases the discovery of solid faeces in the rectum immediately after the bowels have been opened should remove doubt as to the diagnosis. A growth of the rectum or pelvic colon, and less frequently a growth in other parts of the colon, though rarely on the proximal side of the splenic flexure, may lead to false diarrhoea, faeces being retained above the growth, whilst the serous and often blood stained exudation from its surface, mixed with mucus produced by the irritant action of the exudation on the mucous membrane below it, are passed at more or less frequent intervals, so that the patient regards himself as suffering from diarrhoea. The character of the stools should at once make it obvious that endoscopic and radiological examinations are required, even if nothing abnormal is felt on abdominal or rectal examination. In all cases of diarrhoea the history is of great importance in diagnosis. An acute onset suggests an infective cause, but emotional factors must be carefully considered as must any residence abroad or particular dietary indiscretions or idiosyncrasies. A more gradual onset of intermittent diarrhoea in a middle aged individual, who has hitherto been regular or constipated, suggests the possibility of a growth. A careful abdominal and rectal examination should be made in every case. The former may reveal the presence of a tumour or an abnormally dilated or contracted condition of the colon. In any doubtful case a sigmoidoscopy should always be done, as the mucous membrane of the accessible part of the colon is almost invariably involved when diarrhoea is due to some form of colitis, and very frequently when due to growth.

The examination of the stools is of the greatest importance, as it gives valuable indications for treatment as well as helping in diagnosis. In small intestine diarrhoea the stools are watery, at any rate in the early stages, whereas in colonic diarrhoea they are unformed but not fluid. In acute enteritis there may be flakes of mucus floating in fluid faeces which is often blood stained, and microscopical examination shows the presence of red corpuscles, degenerated epithelial cells and pus cells, as the inflammation subsides the mucus becomes cell free and finally disappears. Similarly the unformed, but not watery faeces of an irritable colon can be distinguished from the faeces of colitis by the presence of mucus, pus and blood in the latter. In amoebic dysentery the stools are usually semi solid and very foul smelling with dirty brown mucus and dark blood, whilst in acute bacillary dysentery they often consist of blood and mucus only, the latter being tenacious sticking to the bedpan and odourless.

The presence of excess of starch, meat fibres or fat indicates a small intestine diarrhoea. Excess of undigested starch is found on microscopical examination in fermentative diarrhoea, and of striated muscle fibres in putrefactive diarrhoea. The faeces are often frothy and have an acid smell and reaction when fermentation is excessive, they are alkaline and have a putrefactive odour when excessive putrefaction is present.

Steatorrhoea—The stools passed when fat is insufficiently digested or absorbed may usually be recognised by their pale colour and increased bulk, but it must be remembered that a high stool fat content may be present in spite of a normally coloured stool. Faecal fat analysis is therefore necessary, but simple percentage estimations may be misleading unless the diet is known, since a high residue and low fat diet will lead to a low fat percentage in the dried stool. The pale colour of sprue stools is generally attributed to reduction of the normal stercobilin to colourless stercobilinogen and on exposure to light such stools darken markedly in colour, it must also be remembered that pale stools may sometimes follow an attack of dysentery or other infection even without any excess of fat being present. If the excess is in the form of neutral fat, the stools are oily (*fatty diarrhoea*), and pancreatic insufficiency can be

diagnosed, striated meat fibres are also likely to be present. This condition is, however, rare in the absence of jaundice caused by obstruction of the common bile duct. More frequently most of the fat is present as fatty acid and soaps (*soap diarrhœa*), showing that pancreatic digestion is normal, but that absorption is deficient. This may result from absence of bile salts in obstructive jaundice, and from the sprue-syndrome (*cœliac disease* in children and *sprue* and *non-tropical sprue* in adults). Soap diarrhœa is also caused by obstruction of the lacteals by tuberculous, simple inflammatory or secondary malignant disease of the mesenteric glands. In the latter case the stools become perfectly normal on a fat-free diet, the digestion of meat and vegetable food being unaffected. In soap diarrhœa almost all the calcium in the food combines with fatty acid to form calcium soap and the blood calcium is consequently diminished, so that tetany may result. In children growth is greatly impaired, and deformities result from the softness of the long bones. The inability of the intestines to absorb fat may be associated with deficient absorption of sugar, iron, protein and vitamins A, B, D, E and K, causing *anæmia*, neuritis and severe malnutrition (*malabsorption syndrome*).

Additional investigations—A bacteriological examination should always be made in the hope that the nature of any infection which is present may be discovered, but except in the early stages this is often negative, even in infective cases.

The blood sedimentation rate should be measured in doubtful cases, as in nervous diarrhœa it is likely to be within normal limits, whereas if it is raised organic disease is more likely to be present.

A barium enema should never be allowed to replace careful clinical and especially rectal examination, but is a valuable means of diagnosis in diarrhœa, especially in cases of suspected carcinoma of the colon, even though a rectal growth may be missed by this method. A barium enema will also indicate the degree and extent of an ulcerative colitis, and the presence of diverticula. Radiography after a barium meal may also indicate typical changes in sprue, regional ileitis and other small intestine disorders.

Prognosis—The prognosis of diarrhœa depends upon the cause. The liability to nervous diarrhœa often remains throughout life, but considerable improvement and even a cure can result from treatment. Unlike other forms of diarrhœa, it rarely affects the general health and is chiefly troublesome on account of the inconvenience it causes.

Treatment—The specific treatment of diarrhœa must depend upon its cause, but much may be done symptomatically for the relief of the patient.

Acute stage—The patient should be kept warm and at rest in bed until the attack has subsided. If it is due to food poisoning and he is seen within 12 hours of the onset, he may be given hourly doses of mag. sulph. (1 drachm) for 3 or 4 doses, to clear the irritant material out of the small as well as the large intestine, unless the diarrhœa is so severe that it appears probable that this has already occurred. No food should be given for 24 hours or even longer in severe cases, but the patient may drink as much water as he likes. Sweetened arrowroot made with water should then be given, but nothing else until the diarrhœa has ceased. Milk, junket, bread and butter, eggs and milk puddings are next allowed, after which a gradual return should be made to an ordinary diet, the speed with which this is done depending on the severity of the case. The only symptomatic drugs which are of real use in acute diarrhœa are kaolin and opium and its alkaloids. Two tablespoonfuls of kaolin should be given three times a day or more. If the diarrhœa shows no signs of abating after 24 hours, codeine should be given, the dose being regulated according to the severity of the diarrhœa and the general condition of the patient. The treatment of acute bacillary dysentery is described on p. 117, but many mild cases, particularly of Sonne dysentery, may closely resemble an acute enteritis and respond at once to sulphonamide drugs. The oral use of streptomycin in enteritis is also of value. If there is severe

dehydration from loss of fluid intravenous saline may be necessary, in which case approximately 3 to 4 litres of water containing 3 to 4 g of sodium and 2 to 4 g of potassium will represent an average minimal requirement for 24 hours

Chronic diarrhoea—In all cases of chronic diarrhoea recovery occurs most rapidly if the patient remains in bed during the first few days of treatment. In many instances the diarrhoea, which may have been present for months, disappears in a few days, and the patient may even become constipated. Unless, however, other treatment is instituted, the diarrhoea is very likely to return as soon as he gets up again. As the improvement which results from staying in bed is due in part to the rest and in part to warmth, it is important for the patient to avoid over-exertion and to avoid exposure to cold for a considerable period after the symptoms have disappeared. Patients who have recently suffered from chronic diarrhoea should not go to the tropics, as a slight intestinal attack from bad food is likely to have much more serious results with them than in an individual who has not before suffered from any intestinal disorder.

The successful treatment of chronic diarrhoea depends upon the recognition of its cause, and cases secondary to organic disease of the intestines, such as colitis and cancer, are considered elsewhere.

Whatever the actual cause of the diarrhoea, it is important to avoid anything which could produce mechanical irritation in the colon. The food should be thoroughly chewed and the patient should avoid such things as tough meat, nuts, pips and skins of fruit, whether raw, cooked or in jam, currants, raisins and lemon peel in puddings and cakes and all raw vegetables in salads or pickles, cooked green vegetables should be allowed as purées, meat extracts are often stimulating to bowel peristalsis, and alcohol should only be taken with food and in small amount if at all.

For the treatment of *fermentative diarrhoea*, vide Intestinal Carbohydrate Dyspepsia (p 630).

For the treatment of steatorrhoea see pp 619, 622.

In some cases of diarrhoea in which faecal streptococci are greatly in excess of coliform organisms in the stools, a teaspoonful of a culture of *B. acidophilus* taken fasting every morning or a quarter pint of Yoghurt (sour milk) daily may be successful. Nervous diarrhoea is often completely uninfluenced by diet, but drugs which diminish the activity of the gastro colic reflex either peripherally or centrally, are sometimes effective. A mixture containing gr 5 of sodium bromide and 15 minims of tincture of belladonna taken immediately before meals is all that is required in mild cases. In severer cases a small dose of codeine should be added. The exact dose of each drug should be varied to suit each patient as different individuals react very differently to these drugs, especially to belladonna. Phenobarbitone gr $\frac{1}{2}$, taken half an hour before each main meal is also useful, when the diarrhoea has been completely controlled the quantity of each drug should be gradually reduced and finally discontinued. In some cases it is advisable to allow the patient to have a pill containing belladonna and codeine always with him, so that he can take one before going to a dinner party or on any other occasion when he fears that he will have diarrhoea. He soon learns to trust so thoroughly in his pill that it probably acts more by suggestion than in any other way, and the dose can accordingly be progressively reduced until it is infinitesimal.

THOMAS HUNT

EPIDEMIC DIARRHOEA IN CHILDREN

Synonyms—Summer Diarrhoea, Infective or Infectious Diarrhoea, Acute Gastro Intestinal Infection, Acute Ileocolitis, Cholera Infantum.

The form of diarrhoea here spoken of used to be one of the chief scourges of infant life, but is certainly much less common now than formerly. It prevails epidemically in institutions although sporadic cases may be met with at any time. The

gradually the prostration passes off and the stools assume a normal character. Only too often, however, the improvement is but partial, and the child lapses into a marasmic condition, with continued looseness of the bowels, from which recovery may only take place gradually. In all cases relapses, brought on either by reinfection or by injudicious feeding, are extremely common and apt to prove fatal.

In children above the age of 2 the disease usually assumes a milder form—prostration is not so severe and the range of temperature lower. Vomiting, also, is a less prominent symptom than in infants. Complete recovery is more frequent, and relapses and the continuance of the disease in a chronic form are rare.

In the special type of the disease commonly spoken of as "cholera infantum" the invasion is always abrupt, with a rise of temperature, followed by profuse vomiting and purging. Death usually ensues in a few hours, and is commonly attended by hyperpyrexia.

Diagnosis.—The diagnosis has to be made from simple non-infective diarrhoea, and for the increasingly common forms of diarrhoea secondary to respiratory tract and middle-ear infections. At first the differentiation may be impossible, but continued high temperature, early prostration and failure of rapid improvement on stopping food point to a primary infective origin. Careful physical examination will exclude secondary types. Epidemic prevalence is in favour of the primary variety. The nervous symptoms may simulate those of meningitis, but in case of doubt a lumbar puncture will determine the diagnosis. Very acute cases in which the colon is much involved may resemble intussusception, but in the latter the onset is more dramatically sudden, the vomiting, collapse and passage of blood greater, and fever less, whilst in epidemic diarrhoea abdominal rigidity and tumour are absent.

Prognosis.—It is impossible to give any estimate of the fatality of diarrhoea, as it depends greatly on the type of the disease, and on the age, general condition and surroundings of the child, besides varying greatly in different epidemics. The younger the infant, and the poorer its general nutrition, the worse is the outlook. The existence of rickets also greatly aggravates the danger. The frequency of the stools is of less importance in estimating the chance of recovery in any given case than the amount of prostration and the degree of inelasticity in the skin. Cases with prolonged high temperature and those of the choleraic type usually do badly. Persistence of vomiting also is a bad sign.

Treatment.—Prevention should be given primary consideration in relation to epidemic diarrhoea. The admission of healthy or sick infants to hospitals, homes and institutions of any type must be carefully controlled. When such admission is absolutely unavoidable, isolation facilities are essential and all infants under 2 years should be nursed in cubicles which must be well ventilated. Masks and gowns should be worn by those attending small infants in hospital. Newborn babies should be nursed with their mothers as far as possible and not collected into overcrowded nurseries. The strictest hygiene must be observed by all those looking after small babies in hospital.

Curative measures aim at counteracting the infection and restoring the disturbed metabolism to normal. It is necessary to emphasise that an infant with acute diarrhoea and vomiting is a "medical emergency", just as much demanding admission to hospital for expert treatment as if a "surgical emergency" were present. Such babies should, of course, be regarded as infectious and nursed in isolation with full precautions against spread. A large, airy, well ventilated room in the country rather than the town is to be preferred. On admission, measures to deal with collapse and shock may be necessary. Hot water bottles should be used and a mustard bath is often of help to revive a seriously collapsed child. Drugs such as nikethamide (Coramine) are of value, and brandy has a reputation in this malady for its stimulant powers, although it is fair to point out that it may also have an irritant action upon stomach and bowel. The dose is 15 to 30 minims.

All milk by mouth must be stopped for 24 hours and fluid administered to replace that lost in the stools. This may take the form of half-strength normal saline (sweetened, if necessary, with saccharine) or the more elaborate Hartmann Ringer-lactate solution (also half strength). Glucose or cane sugar additions are inadvisable at this stage. The total fluid intake for 24 hours, given in suitable amounts every 2 or 3 hours, should be on a basis of $2\frac{1}{2}$ oz. per lb. body weight with an extra 5 to 10 oz. to compensate for the dehydration. If the latter is severe, the fluid should be given intravenously. (It is this last procedure which necessitates hospitalisation, regrettable though this may be on other grounds.)

After 24 hours, milk is cautiously started again, while fluid administration is still continued. A choice may be made according to availability and experience between breast milk, half-cream dried milk with or without lactic acid, liquid milk boiled with or without lactic acid, or unsweetened condensed milk. In any case the milk is given *very* dilute to start with, such as 1 part of milk to 8 of saline or Hartmann's solution, the strength being very slowly increased over several days. Similarly the quantities used should begin with 1 teaspoonful and slowly increase to 3 oz. feeds in the course of several days. Additions of sugar should be made with great caution. Dextrimaltose is most valuable at this stage. Great care is needed in starting the child back to a normal diet suitable for the age, and relapses are common, necessitating a return to an earlier stage in the programme. Throughout treatment, in the more serious cases, careful laboratory control is absolutely essential. This implies serial estimations of hæmoglobin and hæmatocrit values and the chemical analysis of sodium, potassium, calcium, chloride and bicarbonate levels of the blood.

Drugs play a minor part in the treatment of epidemic diarrhœa. The initial dose of castor oil to clear out irritating material is not favoured as much as it used to be. Washing out the bowel from below with plain saline in the early stages, and if there is much vomiting, gastric lavage, also with saline, are to be preferred. No intestinal antiseptic, up to recent times, has proved satisfactory, but in some cases certain of the sulphonamides prove helpful. For example, in dealing with epidemic diarrhœa among the newborn, sulphaguanidine has been used in a dosage of 0.75 g. ($1\frac{1}{2}$ tablets) followed by 0.5 g. (1 tablet) 4-hourly for several days. In so far as acute diarrhœa in infants may be due to parenteral infection chemotherapy, including penicillin, may be called for to deal with the primary focus. Although claims are made for the newer antibiotics both for primary diarrhœa and for that due to parenteral infection, carefully controlled experiments have failed to confirm any great value. No drug can replace the need for the general measures, outlined above, so necessary to deal with dehydration and the metabolic disorder present.

For older children, when dehydration is not so serious, the use of bismuth, kaolin and small doses of tinct. opii camph. may be tried.

During convalescence change of air and mild iron tonics are of service in restoring the child to complete health. The diet should contain a generous quantity of vitamins, best in the form of concentrates. Relapses, which are frequent, must be guarded against with the greatest care.

A NOTE ON "MARASMUS"

Mention has been made of the tendency of certain infants, after an attack of gastro enteritis, to pass into a state of marasmus or chronic wasting, for which, up to recent times, no very adequate explanation was available. Thanks to modern developments of biochemical methods, however, it has been possible to prove that some cases of marasmus have an origin in altered metabolism. It must be stressed that the commonest cause of wasting is starvation. This may be quantitative and due to ignorance, for example the use of too dilute a feed, or to a missed 'pyloric stenosis'. It may also be qualitative as seen, for example, in the tropical condition of kwashiorkor.

All milk by mouth must be stopped for 24 hours and fluid administered to replace that lost in the stools. This may take the form of half-strength normal saline (sweetened, if necessary, with saccharine) or the more elaborate Hartmann-Ringer-lactate solution (also half strength). During convalescence change of air and mild iron tonics are of service in restoring the child to complete health. The diet should contain a generous quantity of vitamins, best in the form of concentrates. Relapses, which are frequent, must be guarded against with the greatest care.

A NOTE ON "MARASMUS"

Mention has been made of the tendency of certain infants, after an attack of gastro enteritis, to pass into a state of marasmus or chronic wasting, for which, up to recent times, no very adequate explanation was available. Thanks to modern developments of biochemical methods, however, it has been possible to prove that some cases of marasmus have an origin in altered metabolism. It must be stressed that the commonest cause of wasting is starvation. This may be quantitative and due to ignorance, for example the use of too dilute a feed, or to a missed "pyloric stenosis".

It may also be qualitative as seen, for example, in the tropical condition of Kwashiorkor.

Defective absorption may be present as in celiac disease or fibrocystic disease of the pancreas or in the state of recurrent diarrhoea which may follow an attack of gastro-enteritis. Fever and infection as causes of wasting have also to be excluded. Milary tuberculosis in a small baby, for example, may only be detected by radiogram examination. When all these causes of wasting have been excluded there remain others in which defective metabolism is the explanation. *Infantile renal acidosis* is now one of the best studied. An infant after a few months of poor progress with vague "feeding upsets" begins to vomit, is constipated, the weight falls and the urine is usually found to be alkaline in reaction. The blood chemistry shows an increase in chlorides and a reduction in the plasma bicarbonate. It is thought that the relatively immature renal tubules have not acquired the ability to retain bicarbonate. Additional alkali by mouth in the form of citrates restores the blood chemistry to normal, symptoms disappear, appetite improves and weight is gained. After a varying period the alkali can be discontinued as the metabolism (and renal defect) may right itself. In untreated or persistent cases calcium is deposited in the kidneys to produce *renal calcinosis*. The "Fanconi syndrome" (see p. 1179) is another example of renal leak producing profound metabolic changes including wasting. *Idiopathic hypercalcaemia* is found in some infants presenting a very similar picture to that of infantile renal acidosis but here the blood chemistry shows a raised calcium, often as high as 18 mg and raised blood urea. A low calcium diet and alkalis can be used and there is a slow tendency to recovery in most instances. The exact cause is unknown. Disturbances of carbohydrate metabolism may also cause obscure wasting. Several examples of galactosuria (see p. 444) have now been published in which there is an inborn inability to deal with this sugar. A still rarer variety is sucrosuria in which sucrose is absorbed from the alimentary tract and excreted in the urine. In all these conditions careful examination of the urine, including paper chromatography will often provide a clue, and the blood chemistry is confirmatory. A wide field of speculation is opened up by the consideration of nervous influences in the production of marasmus. Tumours in the hypothalamic region may certainly cause obscure wasting. The possibility of psychological causes cannot be ignored and a better management of the mother child relationship while the child is in hospital may be of importance in this connection.

ALAN MONCRIEFF

CÆLIAC DISEASE

Synonyms—This disease was first described by Gee in 1888 under the title of "The Celiac Affection". Cheadle redescribed it in 1903 as "Achoia", and Herter in 1908 as "Intestinal Infantilism". It is sometimes spoken of in America as "Chronic Intestinal Indigestion", but in this country the term "Celiac Disease" is now generally applied to it.

Definition—A wasting disease of childhood characterised by the passage of large, pale, offensive stools which contain an excess of split fat and leading to emaciation and arrest of growth, various complications due to avitaminosis may be super-added.

Ætiology—The fundamental cause of the disease remains obscure but recent work indicates that gluten in certain flours interferes with fat absorption. There is no hereditary element, girls are more susceptible than boys, and no social class is exempt. The disease appears to be rarer in the Latin countries than in the Anglo-Saxon and Scandinavian.

Pathology—There is no characteristic morbid anatomy, the post mortem changes being attributable to inanition or to intercurrent disease from secondary infection. The bones tend to show changes similar to those of rickets, and the blood chemistry is also similar. The ordinary changes of enteritis are not found.

The general views expressed in the section on idiopathic steatorrhœa can also be studied in this connection. The view that there is a fundamental disturbance of the absorption mechanism, particularly in the upper part of the small intestine, appears to be sound. Radiographic evidence in cœliac disease shows impaired motility of the small bowel, particularly well seen when an opaque meal has been given, clumps of barium can be seen in the duodenum.

Symptoms—The disease begins insidiously between the sixth month and the end of the second year, possibly when wheat flour is first taken. The child loses appetite, fails to thrive and has slight diarrhœa. Soon the characteristic stools appear. They are large, but not necessarily frequent, pale, extremely offensive and sometimes frothy and fermenting. On chemical examination they contain from 40 to 60 per cent of split fat instead of the normal 25 per cent, but the amount of unsplit fat present is not altered. Meanwhile the emaciation progresses the face being least affected by it and the buttocks most. The abdomen, by contrast, is prominent, doughy and distended. Along with these physical signs there is a change in mentality. The child is often remarkably precocious but is irritable, hysterical and "difficult", especially during the exacerbations. There is frequently a profound anorexia, and muscular weakness may be extreme. Anæmia is usually present of the microcytic, iron deficiency type. Very rarely a megaloblastic variety is found.

Complications—Various deficiency symptoms are apt to appear as the result of avitaminosis induced either by impaired fat absorption or by the character of the diet which treatment demands. Rickets may show itself either early or, after the age of 7 in the "late" form, with genu valgum as its main sign. Symptoms such as œdema and absence of reflexes may suggest beriberi and have been attributed to deficiency of vitamin B. Scurvy is not uncommon and attacks of tetany may occur in association with a low blood calcium.

Diagnosis—At the outset the disease may be impossible to recognise, but when the characteristic stools appear diagnosis is easy. Arrest of growth is of great diagnostic value. The distended abdomen may suggest tuberculosis, atonic bowel with fluid feces mimics the signs of ascites. Cœliac disease presents many points of resemblance to sprue but the latter is rare in childhood and in cœliac disease the blood picture is usually that of an iron deficiency anæmia.

A low oral glucose tolerance curve and a low vitamin A absorption curve are both found. The duodenal juice is also normal. This last point is of importance in order to exclude fibro cystic disease of the pancreas. Here the main difference is that there is failure to thrive from birth and, frequently, chronic changes in the lungs.

Course and Prognosis—If untreated or ineffectively treated the disease runs a prolonged course with many ups and downs and is peculiarly prone to relapse. It may persist into adult life (see p 620) but usually tends to recover before puberty. The mortality may be put down at about 10 per cent, and death, when it occurs is usually due to intercurrent disease. During the active phases of the disease growth is arrested, and even after recovery the patient may be permanently stunted (intestinal infantilism). The remarkable results obtained by a strictly gluten free diet completely alter this picture, far more effectively than any previous regime. After a few weeks the child is found to be rapidly proceeding back to normal.

Treatment—The history of the treatment of cœliac disease is marked by varying claims for widely different regimes. Originally a diet high in protein, low in fat and without carbohydrate was recommended. Then the carbohydrate of overripe bananas was found to be well tolerated. Next came the phase of an almost unrestricted diet with whole vitamin B and liver extract by intramuscular injection. Recent work in Holland and England seems to show that the gluten of certain flours especially of wheat, is concerned with the failure of fat absorption so that gluten free diets are now in use in which almost everything else is allowed, even normal amounts of fat. The results appear to be better and more quickly achieved than with any previous

programme Expert dietetic advice is necessary for the mother to secure that no gluten is given, and gluten free flour can be obtained for making "bread", biscuits, sauces etc for which ordinary flour is normally used It is well to admit the child to hospital to establish the diagnosis (excluding especially fibrocystic disease of the pancreas) and to start off the diet with some restriction of fat for a short period Concentrates of vitamins A and D should be given together with ascorbic acid tablets until the diet is going well Iron may be needed if there is anaemia although in a neglected case a blood transfusion is a better way to bring the blood haemoglobin up to normal Folic acid may be used in those rare cases with a megaloblastic type of anaemia Since there is a natural tendency to "cure" of coeliac disease in the course of time a trial should be made after, say, 6 to 12 months of the gluten free regime, to introduce a little ordinary flour while carefully watching the state of the stools If these remain normal in appearance restrictions can be gradually stopped

ALAN MONCRIEFF

IDIOPATHIC STEATORRHOEA

Synonyms—Adult Coeliac Disease, Non tropical Sprue, Gee Herter Disease, Herter Heubner Disease, Gee Thaysen Disease

Definition—This is the adult form of coeliac disease (see above) With certain very rare exceptions it arises in childhood, though some cases remain unrecognised until adolescence or adult life is reached The main features are Fatty stools, with or without diarrhoea, and sometimes with dilatation of the colon, tetany, osteomalacia, anaemia of various types skin lesions and frequently infantilism

Ætiology—This is unknown Adults who in childhood had coeliac disease continue to be intolerant of gluten (see p 618) but the exact mechanism of gluten intolerance is unknown Patients affected have not lived abroad and the disease cannot be classed with sprue, though resembling it in many respects The affection is sometimes familial It is slightly more common in females than in males The disease has been described in the Scandinavian countries, Germany, Switzerland France Great Britain and America

Pathology—The underlying disturbance is interference with the total function of the small intestine Attempts to demonstrate an anatomical lesion have failed even with the microscope The symptoms develop in spite of an adequate diet and the patient starves in the midst of plenty Deficient absorption of various components of the diet explains many of the signs and symptoms The fat although split, cannot be digested and produces steatorrhoea On a low fat diet, the percentage of total fat in the stools forms on the average more than 25 per cent of the total weight of the dried faeces on a normal diet this figure reaches 40 to 60 per cent The fats are mainly split fats the figure for neutral fat not exceeding 3 per cent

Sometimes there is carbohydrate dyspepsia with production of gas which distends the bowel This arises from the bacterial hydrolysis of starch following the failure of amylolytic digestion by succus entericus Sugar is poorly absorbed, and the blood sugar curve after glucose is much flatter than normal Similarly, proteins are ill absorbed and the blood urea is often below normal Poor absorption of salts is seen in the low figure for serum calcium usually 8 mg per 100 ml, and the low or normal plasma phosphorus The height of the plasma phosphatase coincides approximately with the degree of active change in the bones Calcium balance estimations reveal high figures for faecal output and very low figures for urinary output

Defective absorption of iron is followed by hypochromic anaemia, and a macrocytic anaemia, usually due to folic acid deficiency, often appears Occasionally xerophthalmia and toad skin appear, proclaiming vitamin A deficiency Sore tongue

cheilosis, anosmia and pellagra like skin result from shortage of the vitamin B complex. Osteomalacia occurs from deficiency of vitamin D. A tendency to sudden hæmorrhages indicates vitamin-K deficiency. It is associated with a prolongation of the coagulation time and a reduction in the blood prothrombin concentration.

Symptoms—The presenting symptom is either diarrhœa, pain in the bones with deformity or tetany. The stools are bulky and pale, though not always conspicuously frequent. The wasting and distended abdomen so constantly found in children with celiac disease is not a noticeable feature, even though severe diarrhœa be present. The skin shows a dirty putty coloured pallor, and the hair is fine, mud coloured and liable to turn grey at an early age. In 50 per cent of cases a skin eruption is present on the limbs, and to a lesser extent on the trunk. The lesions are moist red abraded areas with scaly brown pigmented borders, resembling pellagra. In 60 per cent of cases the fingers are clubbed. By means of the slit lamp small flaky opacities are to be seen in the various layers of the lens. They never progress sufficiently to interfere with vision.

Most cases show some degree of skeletal deformity, including genu valgum, bending and bowing of the bones, distortion of the pelvis, beading of the ribs and spontaneous fracture. In many of these cases there is dwarfism, but this is not necessarily associated with mental or sexual infantilism. The male genitalia are poorly developed, and the voice high pitched. In women the onset of menstruation is delayed. The disease is usually accompanied by sterility, but should pregnancy occur there is often an acute exacerbation of symptoms. Pelvic deformity may interfere with the normal course of labour. Tetany commonly occurs with recurrent attacks of tinglings in the fingers and hands, followed by carpopedal spasms. These interfere with writing, piano playing and even with walking. In many patients tetany is latent only, its presence being detected on eliciting the Trousseau or the Chvostek signs.

The anemia of idiopathic steatorrhœa is typically macrocytic and may be indistinguishable from pernicious anemia. Erythropoiesis however is more often macro-normoblastic than megaloblastic. Iron deficiency, when present, may lead either to a normocytic hypochromic anemia or may complicate the picture of folic acid deficiency, i.e., a raised mean corpuscular volume may be associated with a low mean corpuscular hæmoglobin concentration. Achlorhydria is uncommon, occurring in less than 20 per cent of all cases. Hæmorrhagic phenomena are rare, even in cases treated for a long time by means of a low fat diet. They include hæmatemesis, melæna, epistaxis, menorrhagia, hæmaturia, hæmarthroses, subcutaneous hæmatomata and intractable bleeding from wounds. Scurvy is very rarely seen.

Radiographic appearances—The intestinal tract shows varying degrees of a deficiency pattern when a flocculable simple suspension of barium sulphate is used. Pronounced flocculation occurs in the upper small intestine and this has been attributed to excessive secretion of mucus. With non flocculable preparations such as Raebars the small intestine appears unduly dilated and hypotonic and its normal feathery pattern is lost. In long standing cases opaque enema examination shows dilatation of the colon, and sometimes this assumes the proportions of megacolon. Radiographs of the skeleton may reveal the changes of osteomalacia, and if the epiphyses have not united the translucent cup like metaphyses of rickets are present. Many cases show fine transverse lines of increased density of bone immediately to the diaphyseal side of the metaphyses of the long bones. Distortion of the limbs, spine and pelvis are common.

Diagnosis—A denial of residence in a country where sprue is endemic is enough to rule out that disease. Other causes of secondary steatorrhœa include chronic pancreatitis, gastrocolic fistula, gastroenterostomy or gastrectomy, regional ileitis, tuberculous enteritis, diverticula or blind loops of the ileum or jejunum, Whipple's disease and neoplastic constrictions of the small intestine.

Prognosis—The results of treatment are disappointing in the adolescent and adult cases compared to what is seen in children. Some respond satisfactorily and remain well under treatment. In others all that is accomplished is the alleviation of one or more symptoms and the temporary offset of the downward progress. It is none the less gratifying to see the great improvement in the anaemia of many of the cases, and the recovery from the pain and disability of osteomalacia in others. Often there is a great change for the better in the mental outlook of the dwarfed, crippled, anæmic patient as he is gradually relieved of his disabilities. Unfortunately one group of symptoms and signs may clear up completely, and yet the patient may die in inanition. Thus extensive, moist, red excoriated skin lesions may heal under treatment with the B vitamins, yet relapses of diarrhoea and tetany may result in the death of the patient, the skin remaining normal.

Treatment—This presents great difficulties. While nothing can be done to remedy the primary defect much care can be given to mitigate as far as possible its consequences. The steatorrhoea must be controlled by a low fat diet. No patient with this disease can be given the amount of fat found in the average diet without risking the occurrence of diarrhoea. The diet should be high in calcium content. The best way to secure a low fat high calcium intake is to use skimmed milk and preparations of calcium caseinate, such as Casec or Laitproto. The items of such a diet include meat, chickeo, bread, a scraping of butter, oatmeal, potato, rice, tea, sugar, skimmed milk, cheese jam, cabbage apple banana and tomato. These items can be arranged as follows: carbohydrate 325 g, protein 90 g, fat 30 g and calcium 2 g. Sometimes gas formation from carbohydrate fermentation is a prominent symptom, and then the intake of starch should be strictly controlled, and the administration of diastase may be useful.

Some patients with idiopathic steatorrhoea have few symptoms and their nutritional state is good. In these a normal diet may be tolerated. In others, symptoms often respond to simple reduction of the fat content of the diet, but when they are severe a trial should be made with a gluten free diet. The tedious and exacting regime which this entails is amply justified when remission is induced and although the value of a gluten free diet is not as firmly established to idiopathic steatorrhoea as it is in coeliac disease improvement undoubtedly occurs in individual patients when other methods have failed. It may still be necessary to restrict fat intake for example from the normal 80 to 90 g in a 2,500 calorie diet to 40 to 60 g per diem. Additional calories can be provided in the form of glucose and milk protein (Casulan).

When tetany occurs, calcium lactate should be given in doses of 5 g three times a day. In emergency 20 ml of a 5 per cent. solution of calcium chloride or gluconate may be injected into a vein, and if administered very slowly no ill effects are produced. Vitamin D should be given in every case in which there are clinical or radiographic signs of rickets or osteomalacia. General ultra violet irradiation is also of value. These measures may relieve bone pain, though any relapse of diarrhoea is liable to interfere with this good effect. Cod liver oil, or any other form of vitamin D in an oily medium, is contraindicated in view of the defective fat absorption. Vitamin D should be given in a solid medium in the form of calciferol tablets, 50,000 units daily. In spite of large doses by mouth, the response is sometimes poor and 10 000 units parenterally at longer intervals may then have to be given. Over dosage can be guarded against by examining the urine with Sulkowitch's reagent.

Treatment of the anaemia must depend upon examination of the blood. When it is hypochromic large doses of iron should be prescribed until the haemoglobin figure reaches normal. This usually occurs with ferrous sulphate gr 6 three times a day. When the anaemia is refractory a satisfactory response may be obtained by means of intravenous or intramuscular iron (see p 733). Macrocytic anaemia usually responds to folic acid 5 mg t d s by mouth. In some patients it may have to be given intra-

muscularly, and in others cyanocobalamin or even crude liver injections may be needed in addition. Whatever the form of the anaemia, it is essential to remember the importance of adequate dosage. For 1 week in each month a prophylactic dose of vitamin K or its derivative should be given by mouth. A suitable dose is 30 mg of menaphthone. If hypoprothrombinæmia has already led to hæmorrhage the vitamin or its synthetic analogue should be administered by injection, double the above doses being used.

Orthopædic treatment includes splinting or even osteotomy to correct deformities, such as genu valgum. A cork sole may be necessary, and kyphosis may demand the use of a spinal jacket. The pelvic deformity may necessitate Cæsarean section.

DONALD HUNTER

TROPICAL SPRUE

Synonyms—Cochin China Diarrhœa, Psilosis, Ceylon Sore Mouth, etc.

Definition—Tropical sprue is a disease of unknown ætiology involving the gastrointestinal tract, characterised by defects in gastric secretion and inability to absorb adequately fat, glucose, calcium and certain vitamins. Typically there is apyrexia, morning diarrhœa with bulky, pale, gaseous, fatty stools, sore tongue, megalocytic anaemia, asthenia and wasting.

Ætiology—The disease is mainly confined to the tropics and subtropics, being especially common in parts of India (Bombay), China and Cochin China, also in Ceylon, Java, the Federated Malay States, Puerto Rico and the West Indies where it was first described by Hilliard in 1759. Adult Europeans and people of mixed European blood living in endemic areas are prone to the disease. Except in Puerto Rico, the native population is rarely affected. Both sexes are susceptible, but it rarely affects people under 20 years of age. A hot, damp climate, especially on the seaboard, favours its development, while certain bungalows enjoy an unsavoury reputation in this regard. Various theories have been suggested to explain its ætiology. Some writers link up vitamin B deficiency with dysfunction in the small intestine as revealed by radiological changes. In sprue, as in a number of other diseases, a deficiency pattern has been described characterised by abnormal segmentation associated with diminished motility and alteration in the outline of the mucosal folds. It has been suggested that those changes are associated with degeneration of the cells in the myenteric and submucosal plexuses (Golden) due to a deficiency in nicotinic acid and possible other components of the B complex.

That it is not a primary deficiency disease is indicated by its frequent occurrence in the best fed Europeans in endemic centres such as Bombay, its almost complete absence from thousands of malnourished prisoners of war in the Far East in whom deficiency diseases were very common, and its occasional onset years after leaving an endemic area. Secondary deficiencies may occur in tropical sprue but these are conditioned by derangement of intestinal absorption or the restricted diet imposed by the patient or his physician after the onset of the malady. There is evidence that a failure of phosphorylation of fatty acids, glycerol and glucose may be the immediate cause of malabsorption. It has also been suggested that riboflavin and nicotinic acid may catalyse the process of phosphorylation, and that intestinal infection, dysentery or even radical changes of diet, might alter the intestinal flora which plays a part in the synthesis of certain vitamins (Leisbman).

The view that sprue is a conditioned or secondary deficiency dependent on lack of some factor or factors which play an essential rôle in the chain of chemical reactions involved both in intestinal absorption of certain food constituents and in the production of liver principle has much in its favour. The possibility that this may be

determined by a changed bacterial flora is an attractive hypothesis which, however, requires verification

Pathology—Morbid anatomy—At necropsy the essential lesion consists of an absence of fat, muscular wasting, a small heart general atrophy of the viscera and alimentary tract consequent on malnutrition, a megaloblastic hyperplasia of the red marrow of variable intensity and atrophic changes in the tongue

Most of the specific histopathological findings described in the intestine in sprue have been due to necrobiotic changes in a tropical climate, but in view of the work of Golden and others further investigation along these lines is necessary—especially in regard to the nerve plexuses

Clinical pathology—The anaemia which is by no means invariably present in the early stages, is megalocytic in type, resembling that seen in pernicious anaemia The Price Jones curve is also similar The colour index is usually 1.0 or higher The blood picture shows numerous megalocytes associated with anisocytosis and poikilocytosis, and in the severer cases polychromasia, basophilic stippling and occasional normoblasts may be observed, megaloblasts are rare Hypochlorhydria or achlorhydria is common, but 75 per cent of cases respond to histamine injection by an increase in HCl secretion The total faecal fat is generally increased (30 to 70 per cent of the dried faeces), but splitting is adequate The glucose tolerance test frequently shows a flat type of curve, or one presenting a retarded rise due to malabsorption, while the blood calcium is decreased for the same reason The blood bilirubin is rarely increased to the extent seen in pernicious anaemia Malabsorption of fat accounts for the excessively fatty stool, while fermentation of glucose within the lumen of the bowel, consequent on defective absorption, underlies its acid and gaseous characteristics The pallor of the stool is due to the transformation of sterco-bilin into colourless leucobilin and to excessive fat

Symptoms—The incubation period is unknown, but patients have occasionally developed sprue within a few months of arriving in an endemic area Many years ago Rogers showed that hill diarrhoea in India sometimes passed into tropical sprue During the War of 1939–1945 epidemics of diarrhoea occurred in Burma in which a variable proportion of the affected troops were recorded as developing tropical sprue Some of these were undoubtedly genuine cases of classical sprue, others undoubtedly were not Often the onset is insidious with (1) loss of energy, dyspepsia and flatulence, (2) rapid loss of weight, (3) sore tongue or buccal aphthae, (4) diarrhoea or looseness of the bowels especially in the early morning It may be months before the typical bulky pale, acid, frothy stools reveal the true nature of the malady Apyrexia is the rule and frequently the temperature is subnormal Once seen, the fully developed picture of sprue makes an indelible impression Such a patient is asthenic, emaciated, mentally taciturn and often severely anaemic, the skin is parched wrinkled and sometimes pigmented over the forehead and malar eminences while the nails are ridged and brittle, the tongue, which is invariably clean may be patchily inflamed, ulcerated and atrophic, while the thin abdominal parietes scantily protect the attenuated coils of gas distended bowel visible beneath Physical examination also often reveals a decrease in the area of the liver dullness this is partly attributable to atrophy and partly to intestinal distension Haemic murmurs may be heard over the heart which is small, while both systolic and diastolic blood pressure is lowered On questioning such a patient often complains of sore tongue and aphthous ulcers made worse by spiced and hot foods of characteristic early morning stools and of abdominal distension and intestinal flatulence generally most marked towards evening and often related to the carbohydrate intake Oedema of the feet, cramps and tetany, associated with Chvostek's and Trousseau's signs, may occasionally be observed Parasthesiae are often complained of and tendon reflexes, especially the knee-jerks, may be absent

Complications.—Pyrexia should always arouse suspicion of some intercurrent in-

fection or complication, the commonest of which is a *Bact. coli* infection of the urinary tract. Often this infection is unassociated with fever, and in cases of advanced sprue the urine should be examined for pus cells and cultured for bacteria. Unlike pernicious anaemia, subacute combined degeneration of the cord is not encountered. Neuritic features are not uncommon, tetany with hypocalcaemia occurs in about 20 per cent. of cases, and occasionally purpuric skin eruptions are seen. Anal fissure and haemorrhoids may develop, while venous thrombosis, eczema and pneumonia are occasionally encountered. Ulcers in the small intestine have been noted in a few cases, and perforation of the bowel has been recorded.

Course.—Prior to modern treatment tropical sprue generally proved to be a very chronic disease, showing spontaneous remission and exacerbations, with a tendency to natural cure only if the patient left the tropics, the disease was often fatal, the causes of death being malnutrition, anaemia and intercurrent disease.

Diagnosis.—The well-established case presents little difficulty, but in the initial stages and in atypical cases considerable clinical experience may be required to make a diagnosis. The differential diagnosis includes other causes of steatorrhoea such as idiopathic steatorrhoea (non-tropical sprue), gastro-colic fistula, tuberculous adenitis, lymphadenoma involving the mesenteric glands, chronic pancreatitis and carcinoma of the pancreas. Diseases like pernicious anaemia, tropical macrocytic anaemia, gastric carcinoma and Addison's disease may also need to be differentiated. A careful clinical, biochemical and radiological investigation may be essential for the differential diagnosis of conditions simulating sprue.

Prognosis.—This largely depends on the co-operation of the patient and the institution of combined modern treatment over an adequate period of time. In the absence of intercurrent disease or complications, patients correctly treated in England are almost invariably clinically cured, and though a proportion of them may relapse the response to subsequent treatments is equally satisfactory; sooner or later radical cure is attainable except in the aged. Unfortunately the same good prognosis cannot be given in the case of non-tropical sprue (idiopathic steatorrhoea). It is now generally permissible to let such patients return to the tropics provided they are otherwise healthy and have been free from symptoms for 6 months on a normal diet.

Treatment.—The essentials of treatment are (1) The institution of alimentary rest by appropriate dietary measures and rest in bed, (2) the treatment of megalocytic anaemia, (3) the reinforcement of demonstrable deficiencies. Both in the primary attack and during relapses these asthenic, poorly nourished patients must be put to bed for 5 to 8 weeks under conditions that ensure mental as well as physical rest, while in Europe warmth and the avoidance of chill are essential. (1) *Dietary*.—Many different diets have been advocated, the best known being Manson's milk treatment and the red meat diet of Cantlie. The latter commenced with 2-oz feeds of lean, minced, underdone steak, which were gradually increased until 1½ to 2 lb were taken daily. As a result of observations on the defective absorption of fat and carbohydrate in this disease, Farley introduced graded high protein, low fat, low carbohydrate diets, the ratios of the three fundamental foodstuffs being as 10 0·3 1·3 and the energy values varying from 600 to 3,000 calories. Red meat is the best source of protein when available, but the defatted dried milk powder (Sprulac) contains similar food ratios and gives very good results if used in correspondingly graded amounts. A coalescent high protein, high vitamin diet with fruit and vegetables is permitted in the fifth or sixth week, and subsequently the amount of fat and carbohydrate is gradually increased. (2) *Anaemia*.—The anaemia of sprue is megalocytic in type and almost invariably responds to adequate dosage of liver extract by mouth, provided appropriate dietetic measures are simultaneously instituted. Maximal reticulocytosis occurs about the seventh to ninth day and the blood regenerates at a rate comparable to pernicious anaemia. For the first month dried extract, equivalent to 1½ lb of fresh

liver daily, should be given orally, in the second month the dosage can be reduced to the equivalent of 1 lb daily, and in the third month to $\frac{1}{2}$ lb. In chronic cases, which have repeatedly relapsed, a maintenance dose of $\frac{1}{2}$ lb liver daily may be advisable for 3 to 6 months after the blood has been restored to normal. Very rarely refractory cases are encountered in which reticulocytosis is submaximal and blood regeneration inadequate. Here oral treatment can be reinforced by parenteral injections of the more crude liver extracts such as Campolon (6 ml daily) for 2 weeks. Davidson reports excellent results with the proteolysed liver extract Hepamino (1 oz daily) in intractable cases. Spies and his colleagues have used folic acid as a substitute for liver therapy, a daily dose of 10 mg given orally for 1 month is advisable, followed by a daily dose of 5 mg for some weeks. Simultaneously a high protein diet should be administered to get the best results. Blood transfusion is only indicated in order to tide a gravely anæmic patient over the latent interval before a response to liver or folic acid therapy is obtained. The anæmia in tropical sprue is generally orthochromic or hyperchromic, but in those rare cases where hypochromia is present some complication should be suspected and iron therapy should be prescribed as well as liver extract. Also whenever the hæmopoietic response is unsatisfactory and the production of either red blood corpuscles or hæmoglobin is not maintained at a satisfactory rate, careful investigation should be made for intercurrent disease or complications. Vitamin B₁₂ may be given successfully in some cases as a substitute for folic acid or liver extracts. It should be administered as an adjuvant to dieting and not as a substitute. (3) *Treatment of demonstrable deficiencies*.—Tetany, with hypocalcæmia, calls for the administration of calcium lactate (gr 30 thrice daily), even more important is a diet low in fat, since calcium cannot be satisfactorily absorbed when there is an excess of fat in the stools. Vitamin D in the form of calciferol may also be prescribed. Vitamin B₁ should be given if there is evidence of neuritis, and vitamin C if latent or overt scurvy be suspected. Many of the deficiency lesions in sprue are derived from deficiencies in the B₂ group of vitamins. Nicotinic acid (50 to 200 mg daily in divided oral or parenteral doses for a week to a fortnight followed by a maintenance dose once or twice weekly) and riboflavine (3 to 5 mg daily orally) are very effective in clearing the lesions of the mouth and tongue. The administration of vitamins will not affect the gut absorption defects. It must be regarded only as adjuvant treatment to the diet and liver therapy. Combined vitamin therapy may be given in the form of various proprietary mixtures, especially as a method of providing maintenance dosage subsequent to the use of individual vitamins.

Bact coli infections of the urinary tract respond satisfactorily to sulphonamide therapy.

Once the sprue patient has regained his health he should continue with a well-balanced diet adequate in vitamins and protein, avoiding alcohol, rich, spiced and sugary foods and condiments. Aperients should be taken with caution, and care exercised to avoid chill and respiratory infection. Sprue relapses may recur after many intervening years of perfect health.

HILL DIARRHŒA

Definition.—A peculiar form of gastro intestinal derangement occurring in Europeans living at high altitudes in India, Ceylon and elsewhere during the hot season, characterised by dyspeptic symptoms, abdominal flatulence and the passage of pale-coloured or white, frothy, fluid stools early in the morning.

Ætiology.—The condition was often reported from the Himalayan hill station of India during the rainy season, and the highlands of Ceylon, Europe and South America, at elevations of 6,000 feet or over. Europeans of both sexes and all ages

are liable, and in some years the condition has affected a large portion of the hill population, as in the Simla epidemic of 1880. The cause has been attributed to bacterial contamination of water with resulting infection of the bowel, as well as to a physiological breakdown of the gastro-intestinal system under conditions of low barometric pressure and high humidity. Somewhat similar epidemics were reported from Burma during the War of 1939-1945 in which classical tropical sprue supervened in some instances, here altitude was not implicated and dietary deficiency and intestinal infection were regarded as possible aetiological factors.

Pathology—Little is known either of the clinical pathology or morbid anatomy of the disease, the nature of which will remain obscure until it has been adequately investigated.

Symptoms—The symptoms are flatulence and abdominal distension associated with morning diarrhoea. Defaecation is urgent and generally first occurs about 5 a.m., subsequently the bowels may be opened four or five times before noon, after which the patient is comfortable. The stools are copious, fluid, pale coloured or white, frothy and generally not objectionable in odour. Often the condition is transient, but if it persists considerable loss of weight may ensue. The stools are said to contain an excess of fatty acids, soaps, undigested food remnants and yeasts, while stercobilin as such is either decreased or absent. These findings are similar to those encountered in tropical sprue, and in view of the marked abdominal distension, intestinal flatulence and gaseous nature of the stools, it would appear that there is defective absorption of certain food elements—especially fat and glucose.

Prognosis—This is good. The only danger is that the condition may develop into sprue, and Rogers states that 20 per cent. of his Calcutta cases commenced with hill diarrhoea.

Treatment—Until more is known regarding the nature of the gastro-intestinal breakdown, treatment must remain empirical. If infective in origin sulphaguanidine or other sulphonamides might well be beneficial. On the other hand, if the gastro-intestinal breakdown is associated with defective alimentary secretion and absorption, bed rest, a high protein diet such as Sprulac and liver extract or folic acid therapy would be advisable.

N HAMILTON FAIRLEY

COLON NEUROSIS

Synonyms—Colon Spasm, Muco Membranous Colic, Irritable Colon.

Intermittent painful spasm of parts of the colon is a common condition in nervous people. Formerly it was frequently associated with the passage of membranes of coagulated mucus but for no obvious reason this condition has become rare since 1914. It was commonly known as muco membranous colitis, but as endoscopic examination showed a healthy mucous membrane and the mucus contains no inflammatory cells unless the patient has been injudiciously treated with irritating purgatives or douches, muco membranous colic is a more appropriate name. In rare cases of allergic origin large numbers of eosinophil cells, sometimes with red blood corpuscles, are present in the mucus.

Ætiology—Colon spasm occurs, especially in nervous individuals, in times of anxiety. It is a psychosomatic disorder, being primarily an exaggeration of normal function with colon motility becoming disordered and uncoordinated and the mucus secretion increased. It is slightly more frequent in women than in men and is especially found in sedentary rather than manual workers, it occurs particularly amongst those who have a hard struggle in life to maintain their positions or responsibilities. Colon spasm is aggravated by unsuitable food, irritating purgatives, over-

smoking and in some cases by allergic, endocrine or reflex organic causes such as cholecystitis or appendicitis

In all cases the underlying mechanism is an undue irritability of the neuromuscular mechanism of the colon mainly brought about by psychological causes, particularly fears, and is one manifestation of an anxiety state. Previous organic colon disease, such as bacillary or amœbic dysentery, may also markedly predispose to colon spasm.

Symptoms—In some cases the patient suffers continuously from abdominal discomfort. In others definite attacks, which are often emotional in origin, occur at intervals of weeks or months. The pain is situated most frequently in the left flank and iliac fossa, and just above the pubes. At the same time the descending and iliac colon are often tender and can be felt as a contracted cord, in which scybala can sometimes be distinguished. Less frequently there is pain and tenderness in the cæcum and ascending colon, which are felt to be more firmly contracted than usual, the condition may then closely simulate appendicitis, but no improvement follows appendicectomy. The passage of faeces sometimes gives temporary relief.

The constipation present in the intervals becomes much more severe during an attack. The stools consist of hard, small scybala, which are occasionally moulded into flat pieces as a result of anal spasm. In mucous membranous colic the mucus is passed as very thin membranous shreds, which may form long tubular casts of the colon which are sometimes rolled into a ball. The mucus may be transparent or opaque or grey-white. The membranes may be passed alone or with scybala; the passage often relieving the pain. They are sometimes mistaken for shreds of mucous membrane or tape-worms.

Various symptoms resulting from the associated neurosis are generally present and the patient tends to become depressed and hypochondriacal.

Intestinal sand, formed of brown granules, irregular in shape and never crystalline, composed of calcium soaps of palmitic and stearic acid and calcium phosphate, is occasionally passed, most frequently in association with mucous casts. It must be distinguished from fragments of wood cells passed after eating excess of pears or bananas.

Diagnosis—It is very important to exclude the spasm which results from organic diseases such as ulcerative colitis, diverticulitis and carcinoma before diagnosing a colon neurosis. A rectal and proctoscopic examination should always be made to exclude local conditions, such as fissure, hæmorrhoids or rectal polyp.

A barium meal usually shows no bowel stasis and a normal intestinal passage except for a streak like shadow in the descending and sigmoid colon due to spasm.

Treatment—Treatment should primarily be directed to dealing with the underlying nervous condition by means of simple psychotherapy. The patient should be discouraged from examining his stools. Aperients should be avoided, as they tend to aggravate the spasm, but the stools should be kept sufficiently soft by means of vegetable mucilages or paraffin (see p. 608). Smoking should be restricted and if it has been excessive, should be entirely prohibited. A full diet should be given, excluding only the coarser forms of "roughage", and care must be taken not to restrict too readily items of food which the patient believes she is unable to digest.

Treatment by colon lavage should only be ordered at the start of treatment and then only with considerable care. It makes the patient too bowel conscious and upsets its normal rhythm. Most of the mucus it brings away is what has been secreted as a protective action of the mucous membrane.

The use of bowel antiseptics is not indicated, and the search for any special food sensitisation is only rarely successful, both skin tests and food elimination diets proving disappointing.

PAROXYSMAL PROCTALGIA (PROCTALGIA FUGAX)

The term paroxysmal proctalgia which, as pointed out by Ryle, is preferable to proctalgia fugax is given to a condition in which short attacks of very severe pain occur in the rectum without demonstrable cause

Ætiology—The condition occurs most frequently in men, particularly doctors, and more often in sedentary than in manual workers. Attacks are specially apt to come on at night and during periods of worry, hard mental work or fatigue. They are often associated with migraine and nervous colon disorders, but are unrelated to hæmorrhoids, fissures, polyps or any other organic disease of the rectum or anus. The condition is almost certainly a violent cramp of the muscles around the rectum or of the rectal muscle itself, and most often begins after the age of 30. It should be regarded as a manifestation of a visceral neurosis but may occur, like cramps in other muscles of the body, without proved psychological cause, when it may possibly be due to unrecognised biochemical changes.

Symptoms—The patient wakes with severe pain in the rectum which rapidly reaches an intense climax and continues for 5 to 10 minutes, during which the sufferer sweats and groans in violent agony. There is no diarrhoea or vomiting, and nothing abnormal can be found on rectal examination. All investigations prove completely negative, including sigmoidoscopy and radiological examination.

Treatment—The main essential in treatment is the diagnosis, since patients often believe that some serious disease is present. In the attack firm upward pressure on the sphincter and was recommended by Ryle, or the injection into the rectum of cold water or air may often be successful. Amyl nitrite is ineffective, and morphine is to be avoided if possible. Measures towards relief of the patient's fatigue or anxiety and general health are important, and over straining at stool or intense physical exercise with much sweating and salt deprivation are to be avoided.

INTESTINAL CARBOHYDRATE DYSPEPSIA

Definition—Intestinal carbohydrate dyspepsia is a condition in which discomfort results from the presence of excess gas in the colon, owing to the fermentation of carbohydrates which have escaped digestion in the small intestines.

Ætiology—Under normal conditions starch is digested by the ptyalin of the saliva and the amylase of the pancreatic juice. The ptyalin is the less important, as it is rapidly destroyed by the first trace of free hydrochloric acid with which it comes into contact in the stomach. Normally starch is completely digested in the upper part of the small intestine so that very little reaches the terminal ileum and none reaches the cæcum. When the rate of passage through the small intestine is excessive, there is time for free starch to be digested, but the starch in intact cells reaches the terminal ileum and cæcum unaltered. Here the amylase penetrates the cells, and the sugars pass into the surrounding media, where they are attacked by bacteria, which are present in very large numbers, and undergo fermentation before there is time for much absorption to take place. The symptoms of intestinal carbohydrate dyspepsia are caused by the carbon dioxide and acetic and butyric acids produced by this fermentation. In some cases there is a history of food poisoning or of some intestinal infection which has caused enteritis. The latter may still be present, but more commonly it has given place to a functional irritability of the small intestine, which results in excessive motor activity. In other cases an obvious or repressed emotional cause has given rise to the initial intestinal hurry.

Symptoms—The chief symptom of intestinal carbohydrate dyspepsia is a wide spread feeling of discomfort and fullness in the lower part of the abdomen, caused

by distension of the colon with gas. Gas in the terminal ileum may cause pain round the umbilicus. During the day gas often collects in the splenic flexure, which is the highest point in the colon; the discomfort produced in this way may be mistaken by the patient for gastric flatulence, and aerophagy often results from his attempt to relieve himself by belching. During the night the gas passes to the rectum, which is then as high as any other part of the colon, consequently the greater part is passed during the night and on waking in the morning. The discomfort is generally increased by meals as a result of exaggeration of the gastro colic reflex. It is often greatest during the night, and is a common cause of insomnia. The excess of gas produces borborygmi, the noise of which may itself be enough to keep a patient awake. The distension of the bowel caused by the gas and the irritation of the mucous membrane by the organic acids may cause spasm, the patient then complains of acute pain. Excessive quantities of odourless flatus are passed, and some relief is always felt after its escape.

The abnormally rapid passage of the chyme through the small intestine can be demonstrated radiographically, even when the irritation of the colon is insufficient to cause any diarrhoea and the radiograph shows no change in the normal rate of passage through the colon. Excess of gas can be seen to be present in the colon and terminal ileum. In severe cases attacks of mild diarrhoea are common, much gas being always passed with the stools, which are acid and have an unpleasant sour, but not putrefactive odour. Very acid stools may give rise to a burning sensation in the anal canal. The diarrhoeic stools contain an obvious excess of undigested vegetable matter, and bubbles of gas may continue to form as a result of fermentation of undigested starch.

A fresh stool should be examined whilst the patient is on his usual diet. The microscope reveals the presence of large numbers of starch granules, which are still within their cellulose envelopes and stain blue with iodine. Few or none are present in normal faeces. In contrast with the stools in pancreatic deficiency there is no excess of fat or striated muscle fibres. The normal enterococci of the colon are present in considerable excess, but the number of *Bact. coli* is not increased and no pathogenic organisms are found. On giving a starch free diet the excess of enterococci rapidly disappears, being not a cause of the condition, but the result of the excellent culture medium afforded by the excess of carbohydrates present. If a small quantity of fresh faeces is mixed with water and incubated for 24 hours, much odourless gas is evolved and can be collected, the faeces becoming very acid. No gas is evolved from normal stools. If the examination of a stool is delayed for 6 hours or more all undigested starch may have disappeared and no further gas is evolved on incubation. In the much less common putrefactive diarrhoea which is caused by insufficient digestion of meat a smaller quantity of foul gas is evolved and the faeces become strongly alkaline.

Treatment.—All root vegetables (potatoes, carrots, onions, beetroot, artichokes, parsnips), green peas and lentils, bananas, rice, tapioca and sago and porridge are prohibited. Bread, toast and biscuits, and puddings containing starch are allowed in small quantities, and there is no need to restrict the intake of sugar. If diarrhoea is present, it is necessary at first to exclude all vegetables and fruit, whether cooked or raw. Within a week the excess of enterococci disappears from the stools, which no longer ferment on incubation. It may be necessary to avoid potatoes and other root vegetables for a considerable period and sometimes permanently.

If a diastatic ferment of vegetable origin is taken with each meal, less restriction in diet is required, as in contrast with the amylase of pancreatic preparations it is very slowly destroyed by the gastric juice so that more digestion of starch can occur in the stomach. It helps particularly in the digestion of prepared starch, and allows more bread to be taken than would otherwise be possible. It is much better to prevent the production of gas than to try to provide for its absorption by such

substances as charcoal, but a sedative such as phenobarbitone, which helps to slow down intestinal hurry may be of assistance in a dose of gr. $\frac{1}{2}$ two or three times a day

ORGANIC DISEASES OF THE INTESTINES

ENTERITIS

ACUTE ENTERITIS

Acute enteritis forms part of the picture in most cases of acute food poisoning (see page 119). Acute gastritis may be present alone when vomiting is severe, more commonly gastro-enteritis occurs with diarrhoea with or without vomiting. The poison is generally so diluted when the colon is reached and its evacuation is so rapid that the colon escapes and gastro-entero-colitis is consequently less frequent. Acute enteritis may also accompany the gastritis of acute infections, such as influenza, and occurs in such conditions as uræmia, as well as from the use of many drugs and chemical irritants.

CHRONIC ENTERITIS

Chronic enteritis is a common sequel of acute gastro-enteritis caused by food poisoning and acute infections. It may follow infestation with worms, especially tapeworms. It is frequently caused by indigestible food, especially among people who take excess of "roughage" in the mistaken belief that it is good for their health. The small intestines are sometimes irritated by food which reaches them without undergoing the normal preparation in the stomach in achlorhydria, and after gastro-enterostomy and partial gastrectomy. Chronic enteritis is frequently caused by irritation produced by the habitual use of aperients, psyllium seeds and drugs such as iron and arsenic. The loss of the antiseptic acid barrier of the gastric juice in achlorhydria may lead to infection of the small intestines by swallowed bacteria when oral and naso-pharyngeal sepsis is present. Lastly, the stasis which results from chronic small intestine obstruction leads to a great increase in bacterial activity with the production of chemical irritants which cause severe enteritis. This explains why diarrhoea is commonly present instead of constipation in chronic obstruction of the small intestine.

As the chief symptom of enteritis is diarrhoea, the diagnosis and treatment of which are considered on pp. 611, 613, it is unnecessary to give a separate description here, but see Tuberculous Enteritis and Typhoid Fever.

REGIONAL ILEITIS

Synonym.—Crohn's Disease

Ætiology.—Regional ileitis is by no means rare. It occurs between the ages of 4 and 40 and is most common in young adults. Males are more often affected than females.

Morbid Anatomy.—The terminal part of the ileum is generally first involved. The disease may spread into the cæcum, and any part of the small intestine and colon may be attacked, sometimes with segments of healthy bowel intervening. The mucous membrane is inflamed and eventually ulcerates, and all the coats of the affected segment become thick, œdematous and rigid. Active inflammation is followed by

fibrosis, and the lumen of the rigid bowel becomes progressively more narrowed. The mesentery is thickened and the lymphatic glands are enlarged. Adjacent parts of the bowel adhere together and fistulae form between them and occasionally open on the surface of the abdomen. Microscopically acute, subacute and chronic inflammation is found with giant cells, so that the appearance closely simulates tuberculosis, with which it was frequently confused in the past. But tubercle bacilli are never found in the wall or lumen of the bowel, and animals inoculated with the tissue never develop tuberculosis. The condition is probably infective, but little is known as to the nature of the infection.

Symptoms—The symptoms are those of progressive small intestine obstruction. The patient complains of attacks of colicky pain of gradually increasing severity and frequency round the umbilicus and in the right lower quadrant of the abdomen, the whole of which is distended with gas. The attacks may be associated with watery diarrhoea and occasional vomiting, but constipation is often present in the intervals. The stools contain occult blood, and when they are loose, shreds of mucus are present.

The affected segment of the ileum may form a sausage shaped tumour, which can be felt in the right iliac fossa. One or more fistulae may open in the right lower quadrant of the abdomen or occasionally below Poupart's ligament and a fistula in ano may develop.

Some pyrexia with slight polymorphonuclear leucocytosis is often present. After a time anorexia develops, and the patient loses weight and becomes anæmic. Occasionally, general symptoms such as lassitude and loss of weight may precede the intestinal symptoms by some months. Clubbing of the fingers may occur. When the condition involves the jejunum severe mal absorption effects follow with marked steatorrhœa, producing a clinical picture closely resembling that of non-tropical sprue.

Radiographic examination should be made hourly from 1 to 6 hours after an opaque meal. In addition to the evidence of small intestine obstruction afforded by the presence of loops of dilated bowel containing fluid and gas, filling defects in the terminal ileum and sometimes in the cæcum may be seen. Most characteristic is the "string sign"—a thin, irregular linear shadow passing from dilated coils of ileum through the filling defect to the cæcum. A better view of the terminal ileum is sometimes obtained after a barium enema, which runs through the incompetent ileo cæcal sphincter.

Diagnosis—Pain in the right lower quadrant of the abdomen associated with distension, local tenderness and possibly a tumour and pyrexia should always raise a suspicion of regional ileitis in addition to subacute appendicitis, ileo cæcal tuberculosis, carcinoma and, when fistulae are present, actinomycosis.

Treatment—The affected segment of bowel should be excised. Simple short circuiting is insufficient, as the disease tends to spread in both directions if it is not eradicated, it may, however be the only course possible when there is extensive lymphatic involvement at the base of the mesentery or as a preliminary operation when fistulae are present. The end results are improved if the short circuited bowel is 'excluded' by cutting across its proximal end. Unfortunately recurrence is not infrequent even after large scale resections.

INTESTINAL LIPODYSTROPHY (WHIPPLE'S DISEASE)

Synonym—Lipophagia Granulomatosis

This rare disease was first described by Whipple in 1907. It is thought to belong to the group of collagen diseases, and the main pathological changes are found in the submucosal layer of the jejunum and ileum. Here, and in neighbouring lymph

glands, large mononuclear cells are found with a peculiar foamy cytoplasm, a chylous ascites may sometimes occur. The disease occurs in men usually between the ages of 40 and 60, and in the cases described has proved fatal in almost every instance.

The main symptoms are loss of weight, and a fatty diarrhoea with abdominal pain, anaemia and often pigmentation and oedema. Arthritis occurs in more than half the cases.

Little is known of the causation and treatment of this disease, but reports suggest that some improvement may follow the use of cortisone.

COLITIS

Inflammation of the colon may be general or localised to one segment. Thus inflammation of the caecum (typhlitis), caecum and ascending colon, pelvic colon, rectum (proctitis), or pelvic colon and rectum (pelvi-rectal colitis) may occur alone, but except in the case of the two last, localisation is rarely absolute.

Although enteritis frequently causes secondary colitis, the reverse is also not very rare, even though the ileo caecal sphincter usually prevents the spread of infection from the caecum to the ileum.

The inflammation is generally limited to the mucous membrane and submucous tissue, but it occasionally involves the deeper tissues and may spread to the peritoneum (pericolitis). The inflammation may be catarrhal or ulcerative, and chronic or acute.

The term *mucous colitis* should be abandoned, as mucus is passed in all forms of colitis, moreover, most cases so diagnosed are not suffering from colitis at all, the excess of mucus being the response of the mucous membrane of the normal intestines to irritation by purgatives or of that of the pelvic colon and rectum to irritation by scybala, or to an anxiety state, as previously described (p. 627).

ACUTE CATARRHAL COLITIS

Ætiology—Acute catarrhal colitis occurs most frequently as a result of food poisoning, either alone or associated with acute gastritis and enteritis. It may also be a symptom of specific fevers and various toxæmias, especially uræmia.

Symptoms—The chief symptom is diarrhoea, the stools being frequent, fluid and offensive, they contain mucus, sometimes traces of blood, but no excess of food residue unless the small intestine is simultaneously affected. Abdominal discomfort is present, and paroxysms of colicky pain are frequent. In severe cases there may be well marked general symptoms with a high temperature and a rapid pulse. As a rule the condition rapidly improves, but it may develop into chronic colitis.

Treatment—The treatment is the same as that for Acute Diarrhoea (p. 613).

CHRONIC CATARRHAL COLITIS

Ætiology—The most common cause of chronic catarrhal colitis is the habitual use of purgatives, which are frequently taken even in the absence of constipation. Infection of the bowels with pathogenic organisms, introduced in the food or water or possibly coming from some septic focus in the mouth, pharynx or appendix, may cause chronic catarrhal colitis, which may also be the sequel of the colitis of some specific infection, such as amebic or bacillary dysentery.

Symptoms—Diffuse discomfort and a sensation of fullness are commonly present in the lower part of the abdomen. Slight attacks of colic may occur, but in many cases there is no actual pain. The abdomen is often somewhat distended and tender. The discomfort is generally worse after meals and is relieved if the bowels are well opened. In infective cases and those following an attack of acute colitis, diarrhoea

is generally present, mucus and occasionally traces of blood being found in the fluid stools, but there is no excess of food residue unless enteritis is also present.

The presence of mucus in the stools is often regarded as sufficient evidence to prove that colitis is present. But it is a function of the healthy mucous membrane to secrete mucus to protect itself against mechanical and chemical irritants. Consequently the unformed, clear mucus passed with hard faeces in constipation does not indicate that colitis or proctitis is present, and the same is true of the mucus passed with fluid stools, when irritating aperients have been taken. On the other hand, pus and red blood corpuscles generally indicate the presence of either ulcerative colitis or carcinoma, though the possibility of hæmorrhoids or polypoid adenoma as the source of the latter must, of course, be remembered.

Treatment.—The food must be thoroughly masticated and should be of an unirritating character. The use of purgatives should be avoided, though liquid paraffin or a vegetable mucilage should be given if hard scybala are passed. In infective colitis a liquid culture of *Lactobacillus acidophilus* may be tried, and a mixture of kaolin and belladonna should be given before meals with the addition, if diarrhoea persists of codeine.

ULCERATIVE COLITIS

Definition.—Ulcerative colitis is a severe inflammatory disorder of part or all of the colon, characterised by rectal discharge of blood, mucus and pus, and constitutional disturbances such as fever, secondary anaemia, dehydration, prostration and loss of weight.

Ætiology.—Ulcerative colitis affects mainly young people, more than half the cases beginning below the age of 30. It occurs particularly in sensitive, shy, over conscientious and emotionally immature individuals, and has undoubtedly a very large psychological background in its causation. A direct onset following severe emotional shock can quite often be elicited, and the disease tends to run a long course with periods of freedom and relapse very similar to that of peptic ulcer. Exacerbations often follow a time of anxiety or emotional disturbance, and experimentally such stimuli can be shown to cause mucosal congestion and muscular spasm in the colon. In one type of case, usually beginning in older people, a long history of constipation and abuse of laxatives precedes the onset of ulcerative colitis. In others the condition undoubtedly supervenes as a form of chronic diarrhoea after an attack of proved bacillary dysentery. Bacteriological examination of the stools has hitherto failed to identify any specific organisms as a cause of ulcerative colitis, though dysentery streptococcal and parenteric organisms have all at one time been regarded as causative agents, no good evidence incriminating a virus infection has yet been produced.

In rare cases an appearance similar to ulcerative colitis results from allergy, but the mucus then usually contains many eosinophil cells and little or no pus. Vitamin deficiency from injudicious dieting over prolonged periods may aggravate the colitis but it is never the primary cause.

Symptoms.—The onset is sometimes acute with severe diarrhoea and fever. More commonly it is subacute and insidious, the first symptom noticed being the passage of blood and mucus, with or without diarrhoea. Even in cases which appear to begin acutely a history can often be obtained of slight intestinal irregularity with the occasional passage of mucus or blood for many months or even years before the onset of severe symptoms.

Diarrhoea is always present, there may be as many as twenty stools, most of which are quite small in the day. Blood, pus and mucus are passed, with semi fluid faeces and also alone. In quiescent periods they may appear to be absent, but microscopic examination of the stools shows that this is not the case. Blood may be passed in large quantities by itself, but it is generally mixed more or less intimately with the mucus and pus. It is bright red and the stools are never black and tarry as are seen

with gastric and duodenal ulcer. It is mostly fluid, but small clots are often present. The mucus is clear, or opaque owing to the presence of pus, membranes are never passed. In most cases small collections of pus are easily recognised with the naked eye in addition to that mixed with the mucus and unformed faeces.

Abdominal discomfort is often, but not always, present. Any severe pain is rare except immediately before defaecation, when colic may occur; this disappears as soon as the bowels are opened, especially if flatus is passed. Tenesmus is unusual and occurs only if the anal canal is involved. The abdomen is often retracted. In acute cases and acute exacerbations, however, it may be distended, a sign of some gravity. Tenderness is often completely absent, even in severe cases, but pressure over the colon, especially in the left iliac fossa, may cause discomfort. When the tenderness is considerable, the inflammation has generally spread to the peritoneum and local peritonitis is present. A moderate degree of muscular rigidity is often found in severe cases, especially if there is any local peritonitis.

In acute cases, and in acute exacerbations of more chronic cases, irregular fever is generally present. Apart from this, the patient has generally a good appetite. The constant diarrhoea leads to progressive emaciation and weakness; but in mild cases the patient may feel so well that he is unwilling to undergo treatment in bed. The loss of blood leads to secondary anaemia, which may be severe, the haemoglobin is often only 50 per cent of normal, and may fall to 20 per cent. In such cases oedema of the ankles and ascites may develop as a result of hypoproteinaemia.

Complications.—In the course of healing, strictures, which may be multiple and of considerable length, may develop, especially in cases of long standing. The symptoms do not alter with the development of the strictures, as the stools are so soft that they pass without difficulty through the narrowed bowel. A narrowing can sometimes be recognised with the sigmoidoscope, but the exact degree and localisation can only be discovered with the aid of the radiogram. A stricture does not require surgery unless it causes sufficient stasis to be recognised with an opaque meal as well as with an enema. Radiography also gives an indication of the extent of colon involved, as the normal "haustration" produced by the constant activity of the muscularis mucosae disappears when it is paralysed by inflammation spreading from the mucous membrane to the submucous tissue. In the majority of early cases the distal half of the colon or the pelvic colon and rectum are alone affected. In addition to the absence of haustration the normal mucosal relief pattern is lost and the outline of the narrow tubular colon may be made ragged by the craters of multiple ulcers. A barium enema must be given with care during an acute phase of the disease, and the rubber tube should be soft and introduced not more than 2 in. from the anus in order to avoid damaging the inflamed rectal mucosa. Healing may also be associated with the development of multiple small polypi from tags of inflamed mucous membrane. They may closely resemble adenomatous polypi to the naked eye, but it is doubtful whether true adenomata ever develop from them. They may, however, undergo malignant degeneration, and secondary carcinoma develops in some 5 to 8 per cent. of all cases of chronic ulcerative colitis.

General peritonitis is a very rare complication, and may be caused either by perforation or direct spread of infection through the wall of the colon. Localised abscesses are also unusual, but may give rise to multiple fistulae-in-ano if they occur in the perianal region.

Non-suppurative multiple arthritis may develop, as it does in bacillary dysentery. Clubbing of the fingers may occur.

Diagnosis—The association of blood in the stools with pus and mucus indicates the presence of an ulcerative lesion in the colon, or of a growth of the pelvic colon or rectum. The latter can usually be excluded by rectal and abdominal palpation, and by the sigmoidoscope. Even if the growth is too high to be reached by the instrument, its presence is rendered very probable when the accessible part of the

colon appears normal, and blood, mucus and pus are seen coming from above. The instrument should be passed with care under visual guidance and without much air inflation, no anæsthetic is required and no force should be used. If there is much difficulty or pain in carrying out the investigation it should be abandoned. In ulcerative colitis the mucous membrane is bright red, thick and sometimes granular. It bleeds very readily when touched, and small submucous hæmorrhages are frequently seen. Its surface is covered with blood stained, purulent mucus, some of which should be removed on a sterile swab for bacteriological and cytological examination. Superficial ulcers are invariably present, but in early cases they may be so small that they are difficult to recognise without a magnifying eyepiece. Later they are large, and are sometimes so extensive that only small islets of mucous membrane are left, which may feel like small, flat polypi on rectal examination, the floor of the confluent ulcers being mistaken for the surface of the mucous membrane. The ulcers are always superficial, with irregular edges, the thick mucous membrane may be undermined. The floor of the ulcers appears greyish-yellow when the blood and mucus are wiped from their surface.

If the patient has been in the East the possibility of amoebic dysentery should be considered, though the absence of such a history does not exclude it, as cases may occur in people who have never been out of England. The endoscopic appearance is so distinct that a definite diagnosis can usually be made from this alone. Small, round, red elevations are seen on the otherwise normal looking mucous membrane, corresponding with the collection of broken-down material in the submucous tissue caused by the invasion of *Entamoeba histolytica*. In the centre of each elevation is a depressed yellowish ulcer, where the submucous abscess has broken through the mucous membrane.

Other conditions which may give rise to difficulty in diagnosis are intestinal tuberculosis (q v), the hæmorrhagic blood diseases, or a foreign body in the rectum.

Prognosis—Very acute ulcerative colitis may cause death in a few weeks. More commonly, it becomes chronic with periodic acute exacerbations, and thus approximates to the ordinary form of ulcerative colitis, in which the onset is insidious and the course very prolonged. In a few cases complete and lasting recovery occurs. The mortality of all cases is between 10 and 15 per cent. Death is generally the result of exhaustion from prolonged diarrhœa, anæmia caused by constant bleeding, and toxæmia.

The commonest cause of relapse is anxiety, which may be either prolonged or acute, when the return of severe symptoms may be quite sudden. Relapses may also occur with acute infections, especially tonsillitis, and with food poisoning, dietetic indiscretions, exposure to cold and damp, and fatigue from mental or physical overwork.

Treatment—(a) **GENERAL**—The most important factors in the successful treatment of ulcerative colitis are confidence, patience and perseverance on the part of both doctor and patient. Even in early cases several weeks of strict treatment are generally required, and in chronic and late cases very much longer periods, up to many months, may be necessary. The patient should be kept at rest in bed as long as there is pyrexia and whilst there is much diarrhœa, but fresh air and some form of occupational therapy are most important during this time. A warm bath once a day may be allowed except during the most acute phase.

(b) **PSYCHOTHERAPY**—Attention must be paid to the emotional make up of the patient and dramatic improvement may follow the physician's simple reassurance, encouragement and explanation of the psychological problems which may be affecting the case. Very much more specialised and prolonged psychological treatment has also been widely advocated in early cases, especially by American writers. Many remarkable recoveries in ulcerative colitis have undoubtedly been due to suggestion and the enthusiasm of the physician in some particular form of remedy.

(c) **DIET**—Too limited a diet results not only in loss of weight and strength,

but the food may contain insufficient iron to compensate for the loss of blood in the stools so that microcytic anaemia develops. The anaemia, malnutrition, and particularly deficiency in vitamins aggravate the colitis, and may lead to serious cutaneous and other complications, all of which respond rapidly to a change to a more liberal diet. Patients with ulcerative colitis often have quite a good appetite, and there is no reason for limiting their allowance of meat and other foods containing no indigestible residue. Indeed a high calorie and high protein diet is advisable, and extra vitamins particularly ascorbic acid, 100 mg daily, and the B complex, especially nicotinic acid 150 mg daily, should be ordered. Fruit is best given in the form of juice and strained purees, and green vegetables as purees. Marmite is a valuable addition. Nuts, pips and foods with a hard residue should be avoided.

(d) **LOCAL TREATMENT TO THE COLON**—Colon lavage is little used and rectal injection of penicillin or sulphonamide drugs have on the whole proved disappointing and less successful than when given systemically, the host of other antiseptic solutions that have at different times been advocated have probably only a mechanical effect in washing away bowel debris. Any large rectal wash out is likely to cause serious discomfort or even danger.

(e) The *Sulphonamide* drugs have on the whole given disappointing results but a course of succinylsulphathiazole, 24 g a day for 5 days or phthalylsulphathiazole, 12 g daily for 5 days, each given at 3 hourly intervals is sometimes followed by a brilliant result.

Penicillin has been used in a number of cases and is worthy of trial. Approximately one third of the cases may be expected to benefit temporarily, the effect probably being largely through relief of secondary streptococcal and other infection. Penicillin should be given intramuscularly in a dosage of not less than 500 000 units twice daily for 5 to 7 days, rectal injection of a similar quantity once a day dissolved in 5 oz of saline may be combined with systemic administration. *Chlortetracycline* and other antibiotics may sometimes be of help but more often prove disappointing.

(f) *Cortisone* and *corticotrophin* have been the subject of extensive therapeutic trials and in primary attacks 200 to 300 mg of cortisone daily for 3 to 6 weeks has given excellent results in about half the cases treated.

(g) **BLOOD TRANSFUSION**—Most patients with ulcerative colitis are anaemic. If this is marked a large transfusion of 3 or 4 pints given slowly by drip is advisable. In less severe cases smaller and repeated transfusions are very valuable and not only improve the patient's general condition but often seem to hasten healing of the colon. It may be worth advising a blood transfusion in cases in which the anaemia is slight or even absent altogether. Iron in the form of *ferri et ammonium citrate*, gr 30 four times a day, may be given even in acute cases.

The improvements reported following the use of vaccines, bacteriophage, intestinal mucosal extracts, thiouracil, folic acid and numerous other substances have probably been mainly due to spontaneous remissions, perhaps partly as a result of the doctor's own enthusiasm.

(h) **SYMPTOMATIC TREATMENT**—When the diarrhoea is severe the patient is likely to become exhausted by want of sleep. A dose of codeine sufficient to keep the bowels from acting more than once in the night should be given at 10 p.m. and a smaller dose before meals two or three times a day. A barbiturate such as phenobarbitone gr 2 or 3 may also be safely used at night but opium may be essential and should be administered as the tinct. opii min 10 to 20 in a bismuth mixture. Injections of morphine should be avoided if possible. Pain is not a common complaint in ulcerative colitis though severe colic due to distension of the bowel with gas may occur shortly before the bowels act. A mixture containing belladonna min 5 to 20 with tr. chloroformi et morphinae Co min 5 and kaolin half an ounce as required may relieve these attacks, and the dose of belladonna may be increased until the mouth begins to become uncomfortably dry.

(i) **AFTER-TREATMENT.**—The danger of recurrence is reduced if treatment is continued until sigmoidoscopy shows no inflammation, even if symptoms have already disappeared for some weeks. Associated conditions, such as oral and pharyngeal infections and anal complications, must be treated, as a relapse may follow an acute sore throat or the development of a peri-anal abscess or fistula-in-ano. Cold and chills are particularly to be avoided. The patient should keep permanently on a low roughage diet and, when necessary, take sufficient Isogel or paraffin to keep his stools soft. He should be helped to solve any problems connected with his home, his business or other matters which are causing anxiety, as there is no doubt about the importance of psychological factors in causing relapse and recurrence.

(j) **SURGERY.**—The possibility of surgical treatment should be considered in every case. It has in the past been undertaken mainly for intractable chronic cases which have been wholly incapacitated for many months or years, but it also has an important place in the treatment of earlier cases which do not respond to medical treatment.

An ileostomy affords complete rest to the colon, and the constant irritation of the mucosa by faeces and decomposing inflammatory exudate, and the frequent peristalsis and spasm which it causes are prevented. The main indications for the operation are as follows:

- (1) In the very rare fulminating cases with high temperature and passage of large quantities of pus and blood, when it offers the only good chance of recovery. The mortality of such cases is high, but if the patient survives the operation, improvement is remarkably rapid.
- (2) When continuous treatment under good conditions for some months has led to little or no improvement, or the patient over the years has become a chronic invalid.
- (3) When fibrous strictures, polypi, fistulae or severe perianal infection has developed.
- (4) In cases of progressive arthritis.
- (5) When severe hæmorrhage is recurrent.
- (6) If malignant degeneration has occurred or is suspected.

If surgery is decided upon, the objective should be total removal of the diseased colon: segmental removal is rarely of lasting benefit. In some cases a combined colectomy and ileostomy may be performed at a single operation, but more usually a preliminary ileostomy is needed. In this case about 1 to 2 in. of ileum are brought out beyond the abdominal wall and a bag is cemented to the skin so that no leakage occurs around the opening. As a rule this causes patients surprisingly little difficulty or inconvenience and they may lead fully normal and active lives.

After the ileostomy has been well established, the final stages of colectomy and perhaps an ultimate abdomino-perineal resection of the rectum should be advised owing to the appreciable risk of malignant degeneration occurring in the diseased colon. This is especially necessary if any strictures or polypi are present. In a few cases it is possible to anastomose the ileum to the rectum provided the latter is sufficiently free from disease.

TUBERCULOUS ENTERITIS AND COLITIS

Ætiology.—Miliary tubercles may be present in the intestines in general tuberculosis, but they have no clinical importance. Primary infection of the bowels from tuberculous milk is not infrequent in children, but is comparatively rare in adults. Secondary infection from swallowing tuberculous sputum is very common, ulceration being present in from half to three-quarters of all fatal cases of pulmonary tuberculosis. The lower end of the ileum and the cæcum, where the rapid passage of chyme along the alimentary tract is first arrested so that there is time for the muco-pus in which

the tubercle bacilli of the sputum are enmeshed to be digested, are the parts most frequently affected.

Symptoms and Diagnosis.—In at least one quarter of the cases no symptoms are present, although extensive ulceration may be found post mortem; in the reverse manner, too, it must be remembered that digestive symptoms are very frequent in cases of pulmonary tuberculosis without any organic intestinal lesion being present. Tuberculous enteritis should be suspected in children suffering from diarrhoea with fever, abdominal distension, enlarged glands, anaemia, wasting and weakness. It should also be suspected when pulmonary tuberculosis is associated with diarrhoea, especially if abdominal pain and tenderness are present and blood is found in the stools. A bad general condition in combination with an apparently not bad pulmonary condition is always suggestive of an intestinal infection. Tubercle bacilli are often present in the stools as a result of swallowing infected sputum even with healthy intestines. In the absence of abdominal pain the diarrhoea in advanced phthisis is sometimes due to the achlorhydria which is commonly present, and as a general rule diarrhoea is a late occurrence in tuberculous enteritis and often indicates an associated involvement of the colon.

The diagnosis may be impossible to make with certainty clinically unless a tumour is present in the right iliac fossa, and this does not occur in more than 30 per cent. of cases at the most. Radiography is often able to provide a definite diagnosis, but in some cases no abnormal changes in the small intestine can be made out at all. A slight or moderate enlargement of the liver is present in rather less than half the cases.

Perforation of a tuberculous ulcer is rare owing to the adhesions which form between the coils of intestine. Cicatrisation of ulcers may lead to single or multiple strictures of the small intestines; as these are incomplete and the contents of the bowel are fluid, obstruction is rarely produced. External adhesions and the formation of bands may, however, lead to acute intestinal obstruction.

What has been described in the past as *hyperplastic tuberculosis of the caecum* is probably a form of regional ileitis (p. 631) in which the caecum is involved as well as the end of the ileum. It was always recognised that the condition was not associated with tuberculous foci elsewhere and tubercle bacilli were never found in the stools; there was in fact no evidence that the condition was tuberculous in origin.

Treatment.—The treatment is that of tuberculosis in general, combined with the dietetic restrictions required for non-tuberculous enterocolitis. Especial care should be taken to avoid the swallowing of sputum, and hydrochloric acid may be given with meals, as for achlorhydric gastritis.

POLYPI OF THE COLON: POLYPOSIS

Ætiology and Pathology.—Solitary polypi of the colon are common and cases with two to twelve or more are not infrequent. Most of these polyps are simple adenomata, and it is estimated from post-mortem studies that they are present in approximately one in every ten people. True polyposis, in which the whole or part of the colon is studded with innumerable polypoid adenomata, is very rare. Most cases of primary generalised polyposis are familial, several members of one or more generations of a family being affected. Less frequently single polypi are also familial. Males are more often affected than females, and the symptoms generally begin before the age of 30.

The polypi usually commence as small flat patches of mucosal overgrowth which soon become polypoid. The polypi which develop in the process of recovery from ulcerative colitis are inflammatory in origin and are not adenomata. They are generally present in small numbers but occasionally a condition simulating generalised polyposis develops.

Both single and multiple polypi show a considerable tendency to become malignant, and the majority of patients with familial polyposis ultimately die of carcinoma. In some cases of carcinoma of the rectum and colon the lesion is grafted on a simple polypous adenoma, but in some 4,000 cases of rectal and colonic cancer examined at St. Mark's Hospital, not more than 1 per cent. showed true polyposis. In early cases of carcinoma an adenomatous origin can sometimes be recognised and in some cases of cancer of the bowel simple adenomata are also coexistent.

Symptoms.—Recurrent passage of bright-red blood, unmixed with mucus or pus, sometimes with and sometimes independent of faeces, is generally the first and often the only symptom. In adults internal haemorrhoids give rise to similar symptoms, but in children polypi are the only common cause. In polyposis diarrhoea develops sooner or later as a result of secondary infection and inflammation, and the fluid faeces are mixed with mucus, pus and bright blood, being indistinguishable from those passed in ulcerative colitis. The haemorrhage may lead to severe anaemia, and the diarrhoea to malnutrition and, when it begins in childhood, to infantilism. Tenesmus and abdominal pain are uncommon.

The polypi can often be felt on rectal examination and can generally be seen with a proctoscope or sigmoidoscope, but occasionally they are situated too far from the anus, when radiography is the only means of making a definite diagnosis. Their exact extent can be estimated by means of an opaque enema which gives a characteristic picture, showing rounded semi-translucent areas in the shadow of the colon. Sometimes they are best demonstrated by inflation of the colon with air after the greater part of the opaque enema has been evacuated.

Polypi are the most common cause of chronic intussusception.

Treatment.—Single and multiple polypi in the rectum and pelvic colon can be removed with a diathermy snare or destroyed by a diathermy cautery through a proctoscope or sigmoidoscope. The specimen must be examined histologically, and further surgical treatment undertaken at once if any evidence of malignant change is found. The patient should be re-examined every 3 months for at least 10 years, so that any new polyp which develops can be destroyed before they have time to undergo malignant degeneration. Multiple small polypi sometimes disappear when treated with X-rays. When the whole colon is involved, the terminal ileum should be anastomosed with the lower end of the pelvic colon, the rest of the colon being excised. The polypi present in the remaining part of the pelvic colon and in the rectum are removed or destroyed by diathermy.

CANCER OF THE COLON

Ætiology.—Primary columnar-celled carcinoma of the colon attacks men with slightly greater frequency than women. It is most common between the ages of 40 and 65, although cases have been recorded in early childhood.

Pathology.—Only a little over 1 per cent. of cases of intestinal cancer affect the small intestine. Of the remainder 50 per cent. are in the rectum and at the pelvic flexure, and 25 per cent. in the iliac and pelvic colon; thus 75 per cent. of cases occur in parts of the colon where the faeces are solid. Nearly half of the remainder are in the caecum and ascending colon. The majority of the cancers are of the scirrhous type with much fibrosis, but those in the right half of the colon are frequently of colloid type with great production of mucous material.

Extension to the peritoneum and secondary deposits in the lymphatic glands, liver and other organs develop later and rather less frequently with cancer of the intestine than with cancer in most other situations, obstruction occurring in more than 50 per cent. of cases before the glands are involved. The prospect of a radical cure by operation, if an early diagnosis is made, is therefore comparatively good.

The rectum has a moderate supply of lymphatics and gives operative results intermediate between gastric and colonic carcinoma.

Symptoms.—The average age of onset of carcinoma of the colon and rectum is between 55 and 60, but the possibility of its presence should be considered whenever an individual over the age of 35, whose bowels have previously been regular, develops constipation or diarrhoea without change of diet or habits, or when a patient of the same age, who is habitually constipated, becomes more so without obvious reason. Constipation occurs earliest in the common annular form of intestinal cancer, which narrows the circumference of the bowel while the actual size of the growth is still very small. Less obstruction is caused by papillomatous carcinoma, which forms a friable and ulcerated mass, projecting into, but not obliterating, the intestinal lumen. Constipation is at first intermittent and relieved by purgatives, which gradually become less effective and cause more pain. Enemata are generally of use for a longer period, but they also finally fail to act. Sometimes, however, there is persistent diarrhoea from the start, especially when the growth is situated in the pelvic colon. More frequently the initial constipation is interrupted by attacks of diarrhoea. In the majority of cases the constipation becomes steadily more severe until it ends in complete obstruction, which is sometimes hastened by the impaction of a hard mass of faeces in the narrowed lumen.

The stools do not generally differ in shape from those seen in ordinary constipation. Occasionally thin pieces, resembling the faeces formed in some cases of constipation associated with spasm, are passed, especially when the growth is in the pelvic colon or in the rectum; they sometimes owe their shape to spasm of the anal sphincter, produced reflexly by the growth or by the irritating discharge from its surface, but may be due to a stricture well above the anus. The stools in cancer of the rectum and lower part of the pelvic colon generally contain obvious blood, pus and mucus. In rare cases the passage of a large quantity of bright-red blood is the first symptom. The stools may closely resemble those of simple ulcerative colitis, but faecal matter is often absent and fragments of more or less solid faeces can sometimes be recognised, whereas in ulcerative colitis unformed faeces are almost always present. When the growth is proximal to the middle of the pelvic colon, blood and pus can rarely be recognised with the naked eye, but occult blood can almost always be found by the guaiac test.

Vague discomfort in the lower part of the abdomen is often present, sometimes without any irregularity of the bowels, and slight attacks of colic occur when constipation becomes severe, but they rarely reach any great intensity until the obstruction is almost complete. In some cases the pain is in the region of the growth, or it may travel towards this point, where the patient occasionally feels a rumbling sensation. When the pelvic colon is involved, the pain is always below the umbilicus and is often most marked on the left side. In carcinoma of the transverse colon the pain is situated above the umbilicus as frequently as below.

The over-activity of the colon above the obstruction leads to hypertrophy of its musculature. When the obstruction becomes complete, failure of the muscle ultimately occurs and extreme paralytic distension results, ulceration and perforation, especially of the caecum, may follow.

When the obstruction is sufficient to give rise to severe pain, strong spasmodic contractions of the colon, but not peristaltic waves, are often visible and palpable. They never occur in the colic associated with lead poisoning or colitis, and very rarely with obstruction due to simple impaction of faeces.

In cancer of the colon, especially the ascending part, or the caecum, general symptoms, particularly weakness and anaemia, are often present for a considerable time before any change takes place in the activity of the bowels. Severe anaemia may indeed, though rarely, develop in the absence of any symptoms pointing to abdominal disorder. This is not the result of massive hæmorrhage, which is rare, but is due

to slight continued loss of blood from the growth, together with the poor appetite and deficient nutrition which is often present. Occult blood is almost always to be found in the stools if this is looked for on several occasions.

In about 30 per cent of cases when the patient is first seen, a tumour is palpable either on abdominal or rectal examination. In some of the remainder the growth is inaccessible to palpation owing to its situation at the splenic flexure, in others it is too small to be palpable. It is often impossible to reach a growth in the lower end of the pelvic colon or at the top of the rectum either by abdominal or rectal examination, though it may be accessible to bimanual palpation. In such cases the sigmoidoscope alone makes an early diagnosis possible. If acute obstruction is not an early occurrence, the growth develops into a large and easily palpable tumour, which invades the neighbouring peritoneum and viscera. The tumour often varies in size from time to time, as it is formed not only by the growth itself, but partly by impacted faeces or by thickened peritoneum and adherent coils of intestine, with perhaps a localised abscess. The disappearance of a tumour after treatment with purgatives or enemata does not therefore mean that cancer is absent, even if its disappearance is associated with improvement in the symptoms. For a mass of faeces can become impacted above a cancerous stricture and produce obstruction, which may be partially relieved when the faeces are removed. A diagnosis of cancer can be excluded only when the disappearance of the tumour is accompanied by complete and lasting cure of all the symptoms. The tumour produced by a growth is hard, it is rarely very tender, unless complicated by local peritonitis. When situated in the ascending, descending or iliac colon it is generally fixed, in the caecum and transverse colon it is frequently very movable.

Radiography often affords considerable help in diagnosis. The shadow of the colon may be visible as far as the seat of obstruction unusually soon after the opaque meal, which, however, should not be given in the presence of obstruction, little or no barium may pass beyond this point for a considerable time, but a similar localised delay may also occur in simple constipation. A barium enema, however, will in most cases demonstrate the presence of a growth either by a failure of the enema to pass beyond the site of the obstruction or by the appearance of a narrowed rigid segment of colon with an irregular outline or an obvious filling defect. Tenderness may also be noted at this site by palpation under screen control, and when an abdominal tumour is present the combination of palpation and radiographic examination shows whether any delay observed occurs in the neighbourhood of the tumour and whether the latter arises from some part of the alimentary canal. Radiography may completely fail to give any evidence of a growth until some months have elapsed since the onset of symptoms, but with modern technique this should happen very rarely.

In exceptional cases symptoms are produced by complications before the intestinal functions become affected. Thus secondary deposits in the brain may cause cerebral symptoms sufficient to overshadow everything else, and an abscess developing in connection with an ulcerated growth or a stercoral ulcer above the obstruction or general peritonitis resulting from perforation of the ulcer may constitute the earliest clinical manifestation. In rare cases distension from ascites is the first symptom noticed, in others jaundice from secondary glands pressing on the common bile duct. It is frequent for a liver much enlarged with metastases to be the first cause of bringing a patient to the doctor, and early symptoms are sometimes ignored or disregarded until the development of a gastro-colic fistula.

Diagnosis.—The diagnosis depends upon the history combined with the results of abdominal and rectal palpation, examination of the stools for visible or occult blood, sigmoidoscopy and radiography. A tumour in the right iliac fossa may be caused by an inflammatory mass developing round a small chronic appendicular abscess, by regional ileitis, tuberculosis and by actinomycosis of the caecum as well as by cancer. In the left iliac fossa confusion with diverticulitis is likely to occur

In the latter occult blood is often absent, tenderness is more marked and the diagnosis can generally be settled by means of radiography. The chronic obstruction caused by a local band of adhesions may simulate that caused by a growth, the difficulty being increased by the fact that the stools may contain occult blood. Many cases are at first wrongly regarded as psychoneurotic, owing to the combination of general weakness and indefinite abdominal symptoms, others are diagnosed as colitis, owing to insufficient or incompetent investigation. The need for an immediate rectal examination in any patient whose symptoms might possibly be due to a carcinoma of the colon cannot be emphasised too strongly, nor must it be forgotten that a normal result on barium enema examination does not rule out a carcinoma of the rectum. In doubtful cases a rapid blood sedimentation rate if found may be of help in pointing to an organic and not a nervous cause of bowel symptoms.

Prognosis—Improved methods of examination have made it possible to diagnose the large majority of cases of cancer of the colon as soon as symptoms appear and before any serious degree of obstruction has developed. As glandular involvement and secondary deposits in the liver and other organs occur comparatively late, in most such cases the growth can be completely removed. At the same time it must be admitted that many patients do not present themselves to the doctor before either metastases have occurred, or acute obstruction has supervened. In the latter case operation has a high mortality. In subacute obstruction preliminary colostomy with later resection is less dangerous, whilst in early cases with modern methods the immediate prognosis is excellent, and the five-year survival rate may be as high as 50 to 60 per cent. The prognosis is better in older patients and in women than in men, and with growths on the right side of the colon than the left. The actual size of the growth is no guide whatever to prognosis, as widespread metastasis may be present with only a very small primary tumour, and vice versa. Soft colloid growths are of bad prognosis, but purely local spread to adjacent tissues does not necessarily make the outlook hopeless. Untreated cases of carcinoma of the colon or rectum receiving symptomatic treatment only, rarely live more than 6 to 12 months from the time of diagnosis, but simple colostomy alone is likely to prolong life by 1 to 2 years.

In general, only about half the cases are resectable when first diagnosed, but even so prognosis of carcinoma of the colon as a whole is at least twice as good as in carcinoma of the stomach.

Treatment—Cancer of any part of the large intestine proximal to the middle of the transverse colon is best treated by the removal of all the colon up to 3 in beyond the growth, an ileo-colostomy being simultaneously performed. Beyond this point resection of the growth and of a sufficient margin on each side with end-to-end anastomosis may be more satisfactory.

With the introduction of sulphonamides and antibiotics it is now possible completely to sterilise the contents of the bowel before operation and with this safeguard to undertake a one-stage abdominal resection with enormously diminished risk compared to earlier days. With careful general preparation and pre medication it is possible to resect the left as well as the right half of the colon with an operative mortality even in advanced cases of less than 10 per cent. In cases of subacute obstruction temporary improvement may be obtained by aspiration of the intestinal contents through a Miller-Abbott tube, and the use of small doses of paraffin and magnesium hydroxide.

In inoperable cases a permanent colostomy may enable a patient to enjoy a considerable period of useful life with relatively little inconvenience from the artificial opening.

All patients after resection of a carcinoma of the colon should be re examined every 3 months for 5 years, especially if there is evidence that the growth developed in a polyp, as so-called recurrences are often really new growths which may in this way be recognised before they have given rise to any symptoms.

DIVERTICULOSIS DIVERTICULITIS

Ætiology and Pathology.—Diverticulosis, the presence of diverticula in the colon, occurs in about 5 per cent of men and women over the age of 40. They are especially likely to develop if aperients have been habitually used for many years. Owing to the atrophy of the muscular coat of the colon which occurs in old age, pressure from within produces diverticula more readily than in earlier life. The presence of fat diminishes the resistance of the intestinal wall, so that diverticula are especially likely to occur in the obese and they often form in the appendices epiploicæ.

The diverticula increase in number and size as the lower end of the pelvic colon is approached, but they are very rare in the rectum owing to the thickness of its muscular coat. A large number are generally present. Some are so small that they are barely visible to the naked eye, whilst others attain a diameter of half an inch. They very rarely become larger than this, as secondary pathological changes interrupt their growth. In the walls of the smaller diverticula all the coats of the bowel are represented. As they grow larger the muscular layer gradually disappears and the mucous membrane frequently becomes atrophied.

Symptoms.—*Diverticulosis*, the simple presence of diverticula of the colon is a very common condition and gives rise to no symptoms. Inflammation of diverticula *diverticulitis* occurs in about 15 per cent of cases. Most frequently the patient complains of discomfort in the lower part of the abdomen and, after a time, attacks of severe pain or colic, which gradually increase in severity and in frequency. The discomfort is generally most marked in the left iliac fossa. At the same time the constipation, for which the patient has taken aperients for many years, may become more severe. Aperients aggravate the pain, which is relieved to some extent by the passage of flatus or fæces. Mucus may be present in the stools, and pus cells can occasionally be discovered on microscopical examination, but obvious and occult blood is generally absent.

The temperature is sometimes slightly raised, and in acute exacerbations it may be very high and accompanied by severe constitutional symptoms with polymorpho nuclear leucocytosis.

The bladder is often irritable, the patient having to pass urine with abnormal frequency. At a later stage adhesions with the bladder may develop, and in rare cases gas and fæces are finally passed *per urethram* owing to the development of a colo vesical fistula, diverticulitis and not cancer of the colon being the cause of the majority of cases of this condition. The actual perforation is a result of inflammation, but when the acute attack of diverticulitis which preceded it has subsided, cystoscopy generally shows that the inflammation is localised to the immediate neighbourhood of the fistula, the rest of the bladder wall being unaffected by the contamination of the urine with fæces. Attacks of subacute cystitis are likely to complicate each recurrence of acute or subacute diverticulitis, but these are often less frequent and less severe than before the fistula developed, the opening into the bladder apparently acting as a safety valve.

Tenderness is most marked in the left iliac fossa and occasionally immediately above the pubes. The rigidity of the abdominal wall over the area may make palpation difficult, but in most cases it is possible to feel the irregularly thickened and tender iliac colon. When a local perforation with pericæcolitis has occurred a fixed, rounded and very tender mass may be felt. Digital examination of the rectum generally reveals nothing abnormal, but a mass may be felt suggestive of a secondary malignant deposit in Douglas's pouch caused by thickening round inflamed diverticula of the pelvic colon. The sigmoidoscope often cannot be passed farther than the pelvic rectal flexure or an inch or two beyond, the bowel at this point appearing to be abnormally fixed and its lumen narrowed.

An opaque meal shows that there is generally little or no delay in the passage through the bowel till the iliac colon is reached. The presence of diverticula can often be recognised when the barium reaches the affected part, as some of it enters and remains in them, often for a considerable time, after the rest has been evacuated. A barium enema should also be given, as whenever diverticula are present their number and localisation can be more accurately determined in this way than by any other method. They may be discovered directly the enema is given, but more often only after it has been evacuated, a double row of small rounded shadows representing the diverticula being then seen, especially in the position of the iliac and pelvic colon. They often remain visible for several days.

Diagnosis.—Discomfort and colicky pain in the lower part of the abdomen in middle-aged and elderly patients, especially if associated with increasing constipation, should raise the suspicion of diverticulitis or a growth of the colon. If the pain is most marked in the left iliac fossa and if it is associated with bladder irritability, the former is the more probable diagnosis. A tender tumour in the left iliac fossa, associated with muscular rigidity is much more frequently due to diverticulitis than to cancer. A radiographic examination after an opaque meal and an opaque enema generally settle the diagnosis. Diverticulitis is not a pre-cancerous condition, as the occasional association with cancer is no more frequent than can be explained by coincidence, and the incidence of cancer in simple diverticulosis is as great as in diverticulitis. The discovery of diverticula in a patient with abdominal symptoms does not necessarily mean that these are the cause of such symptoms, especially if the pain is atypical, or the symptoms point to some other disease.

Treatment.—The accidental discovery of diverticulosis in the course of a routine radiographic examination indicates the advisability of keeping the stools soft by means of an unirritating vegetable mucilage, such as Isogel, and the avoidance of pips and skins of fruit, nuts, pickles, salads, and hard or starchy vegetables. No aperients should be used, as they tend to force the fluid faeces into the diverticula. In mild diverticulitis the same treatment is effective. In more severe cases with pyrexia and abdominal rigidity the patient should be kept in bed till all signs of active inflammation have disappeared. The diet already mentioned should be given together with an ounce of paraffin three times a day. Belladonna in frequent and maximal doses may be required to control the secondary spasm. Six fluid ounces of paraffin should be injected into the rectum every evening and retained during the night. If the bowels do not act satisfactorily in the morning, water should be run into the rectum slowly and under low pressure in quantity insufficient to cause pain. By this means the accumulation of faeces generally present is gradually evacuated, and the pain and inflammation subside. Treatment with sulphonamide drugs and antibiotics should also be given.

Very few cases require operation. Large inflammatory masses associated with a high temperature and leucocytosis often completely disappear following treatment with antibiotics and sulphonamides, and a considerable degree of obstruction may be overcome. Only if the symptoms become worse in spite of treatment, or if the condition is complicated by the development of an abscess or signs of spreading peritonitis, is an operation indicated. It is sometimes possible to excise or short-circuit the whole of the affected portion of the bowel, but more often a colostomy has to be performed.

On theoretical grounds it has generally been assumed that the correct treatment of a colo-vesical fistula is to perform a colostomy at once, and, if possible, to separate the colon from the bladder at a later date. But colostomy does not always result in closure of the fistula, and a fistula may even develop after a colostomy performed for obstruction. A subsequent operation for separating the colon from the bladder is extremely difficult and does not prevent recurrence. A patient with diverticulitis and a colo-vesical fistula is often little the worse for them, and prefers the minor

discomfort which he may have from time to time to the perpetual inconvenience of a colostomy. It is important that he should keep his stools soft but formed; diarrhoea is much more dangerous than constipation, as soft or fluid faeces easily escape through the fistula whereas solid faeces pass it by. He should take no aperients, and should use Isogel instead of paraffin, which makes the faeces too sticky and too liable to enter the bladder. On such a régime little or no faeces may enter the bladder for long periods, although small quantities of gas may escape from time to time without causing any discomfort. The fistula is in fact valvular and generally remains closed for long periods. Should an attack of cystitis develop, rest in bed and the administration of sulphathiazole for 48 hours is generally sufficient to overcome it.

CHRONIC INTUSSUSCEPTION

Ætiology.—Chronic intussusception is a rare disease occurring only in adults. Twenty per cent. are secondary to innocent and 15 per cent. to malignant tumours, most of which project as polypi into the lumen of the bowel.

For Acute Intussusception see Acute Intestinal Obstruction, p. 649.

Symptoms.—A chronic intussusception may last for a month, a year or longer before it terminates in an attack of acute obstruction or of general peritonitis from perforation. It may finally reach the anus, from which it may project for some inches without preventing the passage of faeces. The onset is generally insidious; occasionally it is acute, but the severity of the symptoms generally diminishes and the subsequent progress of the case is chronic. Only about half of the cases are accompanied by constipation, diarrhoea being present in the majority of the others. The most prominent symptom is colic, occurring in attacks which steadily increase in frequency and severity and may be brought on by taking food or by aperients. Constipation is present during the attack, and blood and mucus may be passed at frequent intervals in eotero-colic and colic, but not in eoteric, intussusceptions. A palpable tumour is present in half the cases; it becomes harder and longer during an attack of colic, and appears to recede in the intervals. Severe attacks are accompanied by vomiting, especially in the enteric form. Visible peristalsis and dilatation may occur in the intestines above the intussusception. An opaque enema, given for suspected chronic obstruction, may reveal the presence of an intussusception by the typical appearance produced when a small quantity of fluid penetrates between the intussusceptum and the intussusciptens.

Treatment.—The treatment is always surgical.

MEGACOLON: HIRSCHSPRUNG'S DISEASE

Definition.—Megacolon is a condition in which the rectum and pelvic colon and sometimes the whole of the large intestine are dilated and hypertrophied, although no organic obstruction is present. The condition was described by Hirschsprung in 1887 and occurs in children, untreated cases rarely reaching adult life. It occurs about once in every 30,000 births and shows some familial tendency, being more frequent in males than in females. It must be distinguished from simple dilatation of the colon resulting from constipation, paralytic ileus, obstruction in the sigmoid or rectum, or from gaseous distension in some forms of dyspepsia (q.v.).

Megacolon must also be distinguished from a colon of unusual length but normal diameter—dolichocolon. The pelvic colon varies greatly in length, but although a very long pelvic colon may predispose to volvulus, there is no reason to believe that it predisposes to megacolon.

Ætiology and Pathogenesis.—Recent work has shown that Hirschsprung's disease is due to a congenital aplasia of the ganglion cells of the plexus of Auerbach

and Meissner, in a short segment of the sigmoid colon or rectum. This segment appears normal to the naked eye, but the bowel above it is dilated and thickened. No evidence of inflammation is found, and it is the failure of the aplastic segment to carry on the peristaltic expulsion of the faeces that produces the functional obstruction and enlargement of the colon. This condition is present from birth, and is often fatal before the child is a year old. Other cases of megacolon may develop later in infancy and are due to simple constipation with faecal accumulation in the sigmoid and rectum. Lack of care as to bowel routine, alterations of diet, or painful defaecation are the most frequent causes.

Symptoms.—In Hirschsprung's disease there is always a history of constipation dating from birth or from the first few weeks of life. At an early stage the bowels cease to act spontaneously, and drugs gradually lose their effect until an evacuation can be procured only by means of enemata. The stools are generally soft, but in early cases hard scybala may be passed. Soon after the onset of constipation the abdomen, which is normal in appearance at birth, begins to increase in size owing to distension of the colon with gas and faeces, the size varying from time to time according to the extent to which the bowels are opened. Enormously dilated segments of colon can often be recognised through the stretched abdominal wall; they are dull on percussion, and palpation shows that they are filled with soft unformed faeces. The rectum is empty but a mass of faeces may be felt through the rectal wall in the sigmoid colon. With proper treatment the child can lead an ordinary life without symptoms of toxæmia, but otherwise severe malnutrition and anæmia gradually develop. Attacks of acute obstruction are often superimposed upon the chronic condition.

In cases of megacolon due to faecal impaction the constipation usually becomes complicated by incontinence in which small amounts of soft faeces are continually being extruded past the hard masses in the rectum. On rectal examination hard faeces are felt and rectal prolapse, fissures or piles frequently develop. Constitutional symptoms may be slight and abdominal distension is much less than in Hirschsprung's disease.

Megacolon in adults may give rise to no symptoms beyond a mild degree of constipation. The abdomen is often not obviously distended.

The gas in the dilated pelvic colon is under considerable pressure. In small children it pushes the diaphragm up and the abdominal wall forward, but in older children and in adults the appearance of the abdomen is generally less abnormal, as the diaphragm, which receives no support from above owing to the negative intrathoracic pressure, gives way earlier than the abdominal muscles. In spite of the fact that the diaphragm may thus be almost completely out of action and that the capacity of the chest is much reduced, there is no complaint of dyspnoea, and patients may be able to take strenuous exercise without any difficulty. In most cases the left dome of the diaphragm is alone involved; it may reach the level of the third or fourth rib and is always higher than the right dome. In rare cases the dilated pelvic colon may displace the heart to the right, or cross the mid-line and pass upwards between the upper surface of the liver and the right dome of the diaphragm.

EVERTMENT OF THE DIAPHRAGM.—As the diaphragm in megacolon is displaced into what is normally part of the thoracic cavity, the condition present might with justice be called eventration (*i.e.* out of, "venter," belly) of the diaphragm. This name is, however, generally reserved for a condition in which the high position of the diaphragm is the result of a congenital defect in the musculature of the left half of the diaphragm, which is represented by a fibrous membrane containing only a few scattered muscle fibres. In deep respiration it moves passively up in inspiration and down in expiration—*i.e.* in the reverse direction to that taken by the normal right half of the diaphragm. When the high position of the diaphragm is secondary to megacolon there is a small movement in the normal direction.

The eventration of the diaphragm which results from maldevelopment of its musculature is rare compared with that due to megacolon, other causes being disease or injury to the phrenic nerves and pressure from gastric distension as in *aërocolie bloquée*

RADIOLOGICAL EXAMINATION—Every radiographic examination should begin with an inspection of the patient in the erect position before he has had an opaque meal or enema. The possibility of a megacolon is at once suggested by the discovery of eventration of the diaphragm. The abnormally high position of the left dome of the diaphragm presents such a striking appearance that it can hardly be missed, and as has been pointed out it is more frequently caused by megacolon than by primary atrophy of the diaphragm, in which the left side moves upwards during inspiration while the right side moves downwards in the normal manner. It is generally possible in megacolon to recognise the outline of the enormously dilated air-containing loop of pelvic colon and to distinguish it from an abnormally large gas-bubble in the fundus of the stomach, which is always limited below by the horizontal upper border of the shadow of the gastric contents. When a gas-containing cavity is seen under the right dome of the diaphragm, as well as the left, the diagnosis of megacolon is certain.

An opaque meal does not help greatly in the diagnosis of megacolon, but roentgen examination after an opaque enema gives the only means of recognising the exact anatomical condition present. It is, however, essential to watch the fluid being run in, as it is otherwise impossible to interpret a radiograph owing to the large amount of overlapping of different segments of the bowel caused by the enormous dilatation of the pelvic colon, the uppermost loop of which is often mistaken for the splenic flexure. The fluid is seen to run straight upwards through a greatly dilated rectum and pelvic colon to the left dome of the diaphragm. Small amounts of barium emulsion are run in during screening so that in this way the narrowed segment of rectum and recto sigmoid may be demonstrated distal to the dilated bowel above. Very large quantities of fluid are required to visualise the whole colon and the pelvic colon alone may have a capacity of 6 to 12 pints. The colon in children may hold as much as 4 to 6 pints, and in babies $1\frac{1}{2}$ to 2 pints.

The size of the colon, as shown in a radiograph taken after the injection of an opaque enema, is not an indication of its actual size nor a measure of its tonicity, but an indication of its distensibility. Even if the fluid is injected at a pressure insufficient to cause discomfort, the size of the various segments is often much greater than it is when seen with the sigmoidoscope or after an opaque meal.

Complications.—*Volvulus*.—In a small proportion of cases the patient complains of sudden attacks of very severe pain with abdominal distension. Slight attacks, in which the pain is not very severe and the distension is slight, occur much more frequently, they are probably of the same nature as the severe attacks and are caused by the twisting of a loop of the dilated pelvic colon. Both types of attack may last a few hours or a few days, and almost always subside spontaneously.

Prognosis.—In Hirschsprung's disease the prognosis is bad unless treatment is successfully carried out, and many children die before adolescence. In cases due to infantile constipation the outlook is good, and gradual improvement is the rule as the child grows older.

In many cases megacolon is compatible with perfect health. Most of the patients complain only of constipation no more severe than occurs in many people with no organic disease of any kind, in some the condition is discovered accidentally during routine investigation of abdominal symptoms due to some other cause.

Toxic symptoms are rare unless aperients have been taken in excess. Only in exceptional cases in which radiographs show that severe stasis occurs in the cæcum and ascending colon as well as in the pelvic colon, may true intestinal toxæmia occur.

Treatment—In Hirschsprung's disease the most successful form of treatment

is the operation of recto sigmoidectomy in which the terminal narrowed segment of bowel is removed and the dilated colon anastomosed to the anus with its sphincter mechanism intact. Other surgical measures such as excision of the dilated colon, sympathectomy or the use of spinal anaesthetics have produced only temporary improvement. Conservative medical treatment never leads to lasting cure.

In cases of megacolon due to chronic constipation bowel wash outs should be given for several weeks, preceded, if necessary, by digital removal of faecal masses under an anaesthetic. After the colon has been thoroughly evacuated a magnesium and paraffin emulsion should be given and regular training in bowel habits instituted.

When attacks of pain and distension, presumably caused by a partial volvulus recur in spite of treatment, immediate relief can often be obtained by the passage of a long flatus tube with the patient in the knee-elbow position. If this fails and the pain is severe morphine and atropine should be injected. Relief almost always follows, but if the attacks are frequent and severe, the dilated loop forming the volvulus should be excised in a free interval.

THOMAS HUNT

ACUTE INTESTINAL OBSTRUCTION

Acute intestinal obstruction is a condition in which the passage of the contents along the intestinal canal is more or less suddenly obstructed either completely or in greater part. The blood supply to the involved region is also often obstructed, thus converting something already serious into something critical. Only those forms due to mechanical causes will be dealt with here, those due purely to paralysis or spasm being considered elsewhere.

Ætiology.—The causes of acute intestinal obstruction are numerous, and may best be considered under (1) causes within the lumen of the bowel, (2) causes in the wall of the bowel and (3) causes outside the bowel, while there are two additional conditions—intussusception and volvulus—which do not come under any of these categories.

1. Causes within the lumen of the bowel giving rise to acute obstruction are gall stones, faecal accumulations and very rarely true foreign bodies. Gall stones large enough to cause intestinal obstruction are usually of about 1 inch diameter and enter the intestine, not by the bile ducts but by a fistulous opening between gall bladder and duodenum. The stone becomes impacted where the bowel lumen has narrowed sufficiently, a foot or two above the ileo caecal sphincter. Faecal accumulation may produce an acute termination in a case of chronic obstruction due to some other cause but it may cause obstruction by itself. Then the faecal mass may be enormous in size and of a stony hardness, it leads more frequently to the pseudo diarrhoea of partial obstruction than to complete constipation. The meconium ileus of new born infants is another cause in this category.

2. Causes in the wall of the bowel give rise more commonly to chronic rather than to acute obstruction, the commonest of such narrowings are those due to cancer. These conditions are discussed elsewhere, and it is only their liability to an acute termination which needs consideration here. Such a final catastrophe may result from the impaction of feces, or acute paralysis of the intestinal wall with or without peritonitis may develop. Congenital stricture is a rare cause of acute intestinal obstruction in early infancy, apart from imperforate anus the commonest site is in the duodenum.

3. The most common cause outside the intestine is strangulation of a portion of intestine by congenital or adventitious bands, diverticula or peritoneal adhesions. Such bands may result from old inflammatory disease or may be a sequel to a laparotomy. They may be produced by the adherence of normal structures, such as the

omentum, Fallopian tube or appendix, to other abdominal organs, or may result from the presence of a persistent Meckel's diverticulum. The latter may remain attached to the umbilicus, or its free end may become adherent. Such bands may obstruct by bridging across a portion of bowel, or a knuckle of bowel may become twisted round or under them, or, if the band is not long, mere kinking at its point of attachment may be sufficient to obstruct the lumen. Internal herniæ may give rise to strangulation and intestinal obstruction; their commonest sites are congenital or acquired slits or tears in the mesentery or omentum, one or other of the normal peritoneal fossæ, or, more rarely, the foramen of Winslow, or congenital or acquired apertures in the diaphragm. The peritoneal fossæ into which such internal herniæ may pass are situated in the neighbourhood of the duodeno-jejunal flexure, in the peri-cæcal region, and in the root of the pelvic mesocolon. Since almost always the part of bowel involved in this type is a mobile one, its mesentery is also involved and its blood supply thus greatly endangered. Strangulated external herniæ are, of course, other examples of acute obstruction.

4. *Intussusception.*—By intussusception is meant the passage of a segment of intestine into the lumen of another segment immediately below. When this occurs a tumour is formed consisting of three layers, the outermost or intussusciens being the portion of bowel into which invagination is occurring, and the inner two constituting the intussusceptum, which therefore consists of an entering layer and a returning layer. Between these latter is the strangled mesentery, interference with the vessels of which speedily occurs and induces changes in the intussusceptum. The apex is the distal part of the intussusceptum and the neck the narrow part where the returning layer turns to become the sheath or intussusciens.

Intussusception most frequently occurs in the first two years of life and is then regarded as brought about by irregular peristaltic movements initiated by swelling of the lymphatic tissue on the inner wall of the bowel. In adults an intestinal polypus or carcinoma is often the starting-point of the invagination, which generally differs from that occurring in infants by being chronic instead of acute.

Various forms of intussusception occur, of which the ileo-cæcal variety, with the ileo-cæcal valve as its apex, constitutes about 70 per cent. Enteric, colic, ileo-colic and multiple intussusceptions are less frequent. An intussusception always increases at the expense of the ensheathing layer, its apex remaining constant.

5. *Volvulus* is a condition in which a coil of intestine becomes twisted on itself around its mesenteric axis, leading to interference with its circulation and with the passage of its contents. It occurs most frequently in the pelvic colon and the ileum, but may affect the cæcum or any part of the intestine with a mesentery. The pelvic colon type usually occurs late in life, is commonest in males, and depends partly upon an abnormally shaped mesentery and partly upon loading of the loop from chronic constipation.

Pathology.—In acute intestinal obstruction the conditions found fall mainly into two groups, depending on (1) the occurrence of obstruction of intestine with a previously normal lumen and (2) acute obstruction supervening upon gradually increasing chronic obstruction.

1. In most cases in this group a portion of intestine is strangulated in addition to the obstruction to the lumen of the bowel, and consequently the condition of the intestine must be considered in three regions—namely, above the obstruction, below it and in the strangulated coil itself. An exception occurs in the acute obstruction produced by an impacted foreign body, where, of course, there is no strangulation.

(a) The intestine above an acute obstruction is usually greatly distended, its walls are at first pale and thin, and later oedematous and purple in colour, and the extent of these changes rapidly increases upwards as the obstruction persists. The distended coils are full of fluid (partly the normal dammed-back secretion, partly an exudate of serum), and as the case progresses bacteria escape through the distended and

paralytic coils and lead to peritonitis. These changes are far more marked in small intestine obstruction than when the colon is affected.

(b) Below the obstruction the coils are, as a rule, empty, contracted and pale.

(c) As a result of circulatory interference, the strangulated coil itself becomes distended with effused blood and gas, the latter mainly CO_2 , which cannot be absorbed. It is purple in colour, tense, oedematous and paralysed, and it exudes bloodstained fluid both into its lumen and into the surrounding peritoneal cavity. If the strangulation is sufficiently severe to obstruct arteries as well as veins the coil becomes gangrenous in less than an hour. Such a coil is grey and loses its peritoneal sheen, it is flaccid and exudes free gas and stinking fluid into the peritoneum. This condition is, of course, irreversible, fortunately, complete arterial obstruction does not usually occur for several hours and the intestinal wall quickly returns to normal when the strangulation is released. A strangulated coil soon loses power to prevent the passage of bacteria, and if left alone its vessels inevitably become thrombosed, and its walls become gangrenous and ultimately perforate. The contents of an obstructed loop are profoundly toxic, the toxicity being greater the higher the obstruction is situated.

2. When acute supervenes on chronic obstruction, the bowel has already had time to accommodate itself in some degree to the presence of narrowing of its lumen. The final blockage of the passage is most frequently due to impaction of faeces in the narrowed part, or to locking adhesion, volvulus or acute paralysis of the intestine above it. In such cases the already existing hypertrophy above the obstruction gives place to rapidly increasing distension, and as a result the intestinal circulation is interfered with, and gas, being no longer efficiently absorbed, collects within the bowel. The enteritis and ulceration usually present in some degree above a chronic obstruction rapidly increase, and perforation and consequent peritonitis speedily follow.

Symptoms—The symptoms of acute intestinal obstruction vary somewhat with the particular cause of the condition, but some of them are always present. Of the general symptoms, pain, vomiting, constipation and collapse are the most important.

Pain is an early symptom and is severe, a person in perfect health may be suddenly seized with an acute abdominal pain which doubles him up and never remits. At first the pain is stabbing in nature, but later there are exacerbations which are colicky in character, and which occasionally serve to localise the obstruction. If the condition is allowed to progress until peritonitis supervenes, the continuous pain and tenderness associated with that condition are present in addition.

Vomiting, preceded by nausea and severe retching, usually comes on about an hour after the pain, but it may be delayed for 8 or 10 hours. Once it has begun it continues with increasing frequency, and from the second to the fourth day it becomes stercoral in character. The higher the obstruction, the greater the vomiting, and the sooner does the latter become stercoral. Stercoral vomiting is not due to antiperistalsis, but is caused by the stagnant and excessive secretions of the bowel above the obstruction, gradually extending upward until they overflow into the stomach and cause vomiting. The stercoral character is accounted for by the remarkable speed with which *Bact. coli* and other organisms multiply in the stagnant contents.

Constipation is, as a rule, absolute, although the bowel below the obstruction may empty itself shortly after the onset of the pain and vomiting. Neither faeces nor flatus are passed and enemata, after washing away any faecal material present in the bowel below, are either retained or return slowly without force or flatus.

Collapse is early and severe. The patient is prostrated, anxious and restless, the pulse is rapid, small and thready, the temperature is subnormal and the extremities cold and clammy. The collapse is partly due to a reflex from stimulation of the vagal and splanchnic nerve endings in the abdomen, and partly to loss of fluid from sweating and vomiting. An important part is also played by the toxic intestinal contents, the higher the obstruction the greater is the toxicity of the stagnating contents.

In addition to these cardinal symptoms the patient presents certain other important signs. The tongue is dry and the teeth soon become covered with sordes. The abdomen is at first not tender to the touch, and sometimes pressure may relieve the pain. The higher the obstruction, the less will be the distension. If acute obstruction supervenes on chronic obstruction, visible peristalsis may be present, and the coils can be felt to harden under the hand. Occasionally a tumour is felt in the abdomen, especially in intussusception, where a sausage-shaped mass can frequently be felt. On auscultation intestinal sounds are present in increased intensity, and are high-pitched in character. If peritonitis supervenes the symptoms of that condition develop and consequently the abdominal picture changes. In acute intestinal obstruction the urine is scanty and highly coloured, and when the obstruction is low in the bowel it contains a great excess of indican.

Diagnosis.—The diagnosis of acute intestinal obstruction is usually easy, but the further differentiation of the site and nature of the obstruction, though sometimes fairly simple, is often impossible before operation. The history is of importance in deciding whether the acute symptoms have supervened on those of chronic obstruction, when similar but less severe attacks which were relieved by enemata or purgatives may have occurred. Enquiry should be made for evidence of past abdominal pains suggesting appendicitis, salpingitis or other conditions which might produce bands.

The presence in an infant of a sausage-shaped tumour, which can be felt to harden and is situated usually in the upper abdomen, with tenesmus and the passage of blood and slime, associated with acute attacks of colic causing the child to scream and draw up its legs and with occasional vomiting, forms a characteristic picture of intussusception, and enables a confident diagnosis to be made. In doubtful cases examination under anaesthesia may be required, and rectal examination may enable the intussusception to be felt.

In volvulus the onset is acute, but collapse may be absent. Vomiting is not frequent at first, but the characteristic feature is the rapid onset and extreme degree of distension. This distension may at first be localised and indicate the seat of the volvulus, but it soon involves the whole abdomen and may cause severe cardiac and respiratory embarrassment.

Distension implies interference with the blood supply and consequent deficient absorption of gas from the bowel; it may be a valuable indication as to whether strangulation has taken place as well as intestinal obstruction.

The conditions from which acute intestinal obstruction have to be differentiated are numerous. The most important is strangulated hernia, and a careful examination of the hernial apertures must always be made. In fat patients with femoral hernia it is easy to overlook the condition, and in the rare obturator hernia diagnosis is frequently only possible on opening the abdomen. Faecal impaction is another important condition to be considered, particularly in view of the grave results of laparotomy mistakenly undertaken for its relief. The history of chronic constipation and the presence of hard or putty-like masses in the rectum or pelvic colon should prevent errors. Digital examination of the rectum should never be omitted in acute obstruction, since such masses or a growth may be palpable.

The differential diagnosis from acute peritonitis may be difficult. The extreme tenderness and rigidity in the latter, the absence of stercoral vomiting, the partial nature of the constipation at first, as well as the temperature and history are distinguishing features. Difficulty may arise from conditions causing acute stimulation of the sympathetic nerve, such as torsion of the testicles, ovary or omentum, or the passage of a renal or biliary calculus. Careful enquiry of the history, the characteristic distribution of pain in the colics, examination of the scrotum and vagina and of the urine will usually lead to a correct diagnosis. Further, in these conditions enemata generally result in passing of flatus, and the course of the disease does not follow the

usual sequence in acute intestinal obstruction. In acute pancreatitis the pain is localised in the epigastrium and constipation is usually not absolute.

Lead colic can be distinguished by the blue line on the gums, the history, the blood picture, the absence of stercoral vomiting and the result of enemata; a routine neurological examination will distinguish tabetic crises.

Rare conditions which may lead to mistakes are embolus or thrombosis of the superior mesenteric vessels. In embolus some cardiac lesion is usually present, and in thrombosis there may be evidence of cirrhosis, gall-bladder disease or thrombosis of other veins, while hæmatemesis and melæna are common in both conditions.

Prognosis.—Spontaneous cure is remotely possible in all cases of intestinal obstruction, but in the majority, if operation is not undertaken, death occurs. This termination may be at a variable time after the onset, the average being after 6 days. Once the obstruction has been relieved by operation recurrence is uncommon, excepting perhaps where the cause was peritoneal bands following a previous operation. Even when operation is undertaken, acute intestinal obstruction has a grave outlook, depending partly on the length of time elapsing before intervention and partly on the nature of the lesion. Other conditions materially affecting the prognosis are the age and general condition of the patient, and the presence of toxæmia, septicæmia, peritonitis or complicating conditions elsewhere.

Treatment.—Excluding cases of fecal impaction the treatment of all cases of acute intestinal obstruction is immediate operation. The object of the surgeon is to locate the seat of the obstruction, and to relieve it as quickly as possible with the minimum of handling and exposure of the abdominal contents. When the abdomen is opened a collapsed portion of gut is sought, as this helps to localise the seat of obstruction. When found, the obstruction is relieved in the simplest possible manner, by reducing a hernia, dividing a band, reduction of an intussusception by manipulation, removing a gall-stone, etc. Where simple measures are insufficient, as where the bowel is not viable or a carcinoma is the cause, further immediate procedures depend upon whether small or large bowel is implicated. In the large bowel, resection and anastomosis must not be attempted; the risk of leakage from the suture line is too great. In cancer cases either a proximal colostomy or cæcostomy is made to give immediate relief, the opening being made far enough from the site of the growth to allow a clean field for later deliberate resection, or the growth and adjacent bowel are mobilised and exteriorised, to be cut away after closure of the abdominal wall, thus leaving a double colostomy which is closed when the upper distended bowel has regained normality. Strangulated large bowel is rarely found and is similarly exteriorised. In the small bowel, however, external openings are to be avoided because great loss of fluid ensues and the contained secretions digest the skin around such fistulæ. Resection and anastomosis here carry much less risk of leakage and can usually be confidently performed. Apart from operation, saline and glucose solution should be given intravenously by the continuous drip method to combat the loss of chlorides and fluid, and opium may be given to relieve pain once the diagnosis is established and operation agreed to. As a preliminary to operation, distension should be to some extent relieved by the passage of a Ryle's tube into the stomach with intermittent or continuous suction. The passage of a Miller-Abbott tube farther down the intestine will accomplish this even more satisfactorily but it is often a difficult matter to pass this instrument in a sick patient and, while it may be attempted with advantage, it should not be persisted in.

APPENDICITIS

Ætiology.—The two sexes are affected equally. No age is exempt, but the disease is most common in young adults.

The appendix may become infected either by organisms spreading from the lumen of the cæcum or conveyed by the blood. In the former, the original infection may presumably come from infected food, but septic foci in connection with the teeth, tonsils and naso pharynx are probably of more importance. The latter are also the likeliest sources of hæmatogenous infection. The commonest organism is *Bact coli*; next in order of frequency come streptococci and staphylococci. Congenital or acquired abnormalities are present in a considerable proportion of cases. In the former the appendix is not fully descended, is of the infantile variety or is twisted on itself. In the latter there are adhesions or kinks caused by previous inflammation either of the appendix itself or of neighbouring organs. Obstruction to the lumen from any of these causes produces stagnation of the contents and provides the necessary conditions for bacterial invasion. Foreign bodies are another cause, but they occur less frequently than might be expected. Intestinal worms, pins and fruit pips and stones have all been met with, but by far the commonest foreign body is the so-called "appendicular concretion", formed of inspissated faecal material moulded into shape by the appendix itself.

ACUTE APPENDICITIS

Pathology.—In catarrhal appendicitis the mucosa only is affected, but in the commoner diffuse type all the coats are involved, the organ being hyperæmic, rigid, tense and swollen, and the mucous membrane frequently ulcerated. Later the lumen of the appendix becomes filled with pus, and, if there is obstruction, empyema of the organ results. Later still, local or general gangrene occurs, the most frequent sites being the tip or the base. Perforation is very liable to take place at any of these stages, leading either to a localised appendicular abscess or to generalised peritonitis. The chief factor in determining which of these two complications will occur is the virulence of the organism, since it requires time for the reaction of the peritoneum to come into play sufficiently to localise the results of perforation to the immediate neighbourhood. If the lumen of the appendix is obstructed by a stercolith, acute appendicular obstruction results, and the tension of decomposing faecal matter within its lumen leads to rapid gangrene and perforation. In milder cases the inflammation tends to resolve, and the appendix may return to an apparently normal condition, but if the attack has been at all acute, either adhesions or narrowing of the lumen generally remain, leaving it far more liable to further attacks of inflammation. If perforation and abscess formation occur and operation is not undertaken, spreading peritonitis results. Suppurative pylephlebitis may result from spread of infection along the mesenteric veins either with or without perforation of the appendix.

Symptoms.—In nearly all cases the following symptoms are present, though they may vary in degree:—(1) sudden abdominal pain, (2) pyrexia, (3) increased pulse-rate, (4) gastro-intestinal symptoms, (5) local signs.

1. *Sudden abdominal pain.*—The onset is usually sudden, the patient being seized with severe abdominal pain which is typically central or generalised at first, later moving to the right iliac fossa. In the obstructive type, colicky pain marks the onset, unassociated with fever or increase of pulse rate, and continues until perforation results or operation is undertaken. In very severe cases, especially in children, and where early gangrene occurs, the pain may be comparatively slight after the initial onset, and in other cases the affection may progress to abscess formation with relatively little pain. Such types are, however, the exception and pain is usually a prominent symptom.

2. *Pyrexia* is almost always present at some time during the attack, except in cases of the obstructive type, where its absence is apt to lead to mistakes in diagnosis, but its height is no measure of the severity of the lesion. There is sometimes a rigor

at the onset but the temperature is rarely greater than from 100° to 102° F. A rise only to 99° or 100° F. is not uncommon but is important, as some pyrexia is almost invariably present at some period during an attack. When a localised abscess has formed, and in very severe cases with perforation and generalised peritonitis, the temperature may be normal or subnormal throughout.

3 The *pulse rate* is usually increased and tends to continue to increase as the disease progresses. In cases of appendicular obstruction there may be no increase in the pulse rate until perforation has occurred.

4 *Gastro intestinal disturbances* are almost invariably present. The tongue is furred and rapidly becomes dry. There is usually vomiting at the onset of the attack but it does not precede the pain and, though it persists in the severe cases with peritonitis, it may pass off although nausea usually continues. While constipation is the rule, diarrhoea sometimes occurs and indicates usually a pelvic position of the appendix, in which the inflammation spreads to and irritates the rectum. If the process does not settle and is allowed to progress, complete constipation resulting from peritonitis and consequent paralysis of intestinal movements ensues.

5 *Local signs*—There is usually no distension of the abdomen at the onset of the attack but on inspection it will be seen that the lower abdomen moves less freely than the upper on respiration, and the right side less than the left. There is frequently hyperæsthesia of the skin in the right iliac fossa, and occasionally some œdema can be discovered by loosely picking up the skin and subcutaneous tissues between the fingers and comparing with the other side. There is great rigidity of the right rectus muscle and this is probably the most important single sign, the rigidity is often too great to allow of any proper deep palpation. In addition to the rigidity there is great tenderness and pain on palpation, which has its maximum at MacBurney's point, situated at the junction of the outer and middle thirds of a line drawn from the anterior superior iliac spine to the umbilicus. In some cases an ill defined mass can be felt in the right iliac fossa, and the longer the history the more likely is such a mass to be present. It is constituted mainly of adherent coils of intestine and omentum surrounding the inflamed or perforated appendix. Rectal examination is often of value and sometimes a tender mass can be felt on the right side of the rectum when none can be made out from above. Considerable irritability of the bladder may be present, especially where the appendix is pelvic in position, and the urine, which is scanty, frequently contains albumen.

A blood count is often of value for purposes of differential diagnosis, and usually shows a leucocytosis of from 15,000 to 20,000.

In many of the worst cases, some or all of these signs and symptoms may be absent, but with a careful examination and a clear history it is usually possible to reach a correct diagnosis.

Sometimes an abnormally situated appendix gives rise to characteristic symptoms. With a retro cæcal appendix, local signs in the right iliac fossa may be absent, there being instead great pain and tenderness in the loin, and rigidity without great tenderness of the right rectus. These cases are specially apt to develop subdiaphragmatic abscess. An appendix running down into the pelvis is apt to give diarrhoea and bladder irritability, local rigidity may be slight and a mass can usually be felt per rectum. An appendix running directly inwards may occasionally give rise to left sided symptoms.

Course—Where a correct diagnosis is made, operation should be undertaken at once for reasons to be discussed later, but if operation is delayed the case may take one of three possible courses.

(a) *Gradual recovery* may ensue and in first attacks this will occur in a large number of cases. Improvement begins about the second or third day and the acute symptoms generally subside in a week. Similar recovery may occur, taking a few

weeks, where a mass is palpable. The mass in this instance is due to œdema of the walling off structures, particularly the omentum, although there may conceivably be a little pus which is absorbed in the centre of the mass. In all these cases the patient is extremely liable to have further attacks, a liability which is increased in proportion to the degree of change which has occurred in the appendix.

(b) Often as the result of ulceration or perforation of the appendix, the local symptoms not only do not disappear at the end of the first week, but persist and become aggravated. The temperature usually rises and there may be rigors, while at the same time a tumour becomes palpable in the iliac fossa. In some cases the abdominal wall may become œdematous and indurated and the patient frequently begins to lose weight rapidly, to sweat profusely and to show all the signs of closed suppuration. If an operation be now performed, an abscess is found with walls composed of adherent and matted intestines, omentum and parietal peritoneum. Such abscesses often contain large quantities of very foul smelling pus and if left alone may burst into the rectum or general peritoneal cavity, or more rarely on to the surface, usually in the neighbourhood of the umbilicus. Spontaneous recovery may follow rupture into the rectum or on to the surface, but death is likely to ensue where the rupture occurs into the peritoneal cavity.

(c) The third result of an unoperated attack of acute appendicitis, and by far the commonest cause of death in this disease, is generalised peritonitis. This may occur either from perforation of the appendix before limiting adhesions have had time to form as in cases of the obstructive type, or it may occur without any perforation at all. In the latter instance bacteria pass through the wall of the inflamed appendix and set up suppuration in the neighbourhood, if the resistance is poor, this involves the neighbouring peritoneum and ultimately leads to a generalised infection. In other cases a localised abscess may form and later burst into the peritoneum, a result often precipitated by sudden exertion on the part of the patient, injudicious palpation or the administration of aperients. The great danger of appendicitis, and one that can only be met by immediate operation, is that general peritonitis may occur from the very beginning, and its symptoms may be indistinguishable from those of the acute appendicitis itself. In the hands of competent abdominal surgeons, operation in the early stages is one of almost absolute safety, and in these circumstances any delay, with the shadow of possible peritonitis menacing the patient at any time, is quite unjustifiable.

Diagnosis—As appendicitis is by far the commonest acute inflammatory condition occurring in the abdomen in people under middle age it must always be thought of in the presence of acute abdominal disease. In a typical case, with acute onset of abdominal pain generalised at first and later settling into the right iliac fossa with vomiting, constipation and local rigidity and tenderness, the diagnosis is easy but one or more of these signs may be absent and then it is well to remember that a single positive sign is worth several negative ones. The most constant single sign is tenderness on deep pressure in the iliac fossa and if this is present even in moderate degree, the patient must be carefully watched before a diagnosis of acute appendicitis can be safely discarded.

A general examination is essential in order to eliminate certain other conditions which sometimes lead to mistakes. Right sided pneumonia may cause difficulty, as its onset is sometimes associated with considerable pain and rigidity in the right side of the abdomen but as a rule the accompanying respiratory symptoms and signs especially the rapid respiration, will prevent error. In children, contraction of the right psoas muscle with flexion of the hip may suggest an acute arthritis or even a psoas abscess whilst a psoas abscess is occasionally mistaken for appendicitis. Of the abdominal lesions most likely to cause confusion the most difficult to differentiate is acute tubo-ovarian disease in women. In some of these cases appendicitis co-exists from spread of infection, and where doubt remains after a thorough pelvic

examination it is safer to operate than to risk leaving a possible acute appendicular lesion

In perforation of gastric or duodenal ulcers, the general shock is more profound, the rigidity is more general and board like, and the pain is diffuse and not localised, in biliary and intestinal colic, the nature and distribution of the pain usually suffice to prevent mistakes. The urine should be routinely examined and pyelitis and renal colic excluded by the findings and by the site of the pain. Twisting of a small ovarian cyst may be impossible to differentiate, but operation is called for in either case. In certain cases of typhoid fever the clinical picture may closely simulate appendicitis. The relatively slower pulse and higher temperature, the constant headache and the absence of any definitely acute onset, are of the greatest help in distinguishing and a leucocyte count may be of considerable assistance, as leucopenia is present in typhoid fever in contrast with the leucocytosis of appendicitis.

Prognosis—If left alone a considerable proportion of patients with acute appendicitis tend to recover, but it is not possible to give an accurate prognosis of the course in any particular patient within the first 48 hours. The chief cause of death is peritonitis and less often pylephlebitis septicaemia or pulmonary embolism. Even if recovery from a first attack does occur, the patient is left with a far greater liability to subsequent attacks. Successive attacks of appendicitis tend to be more severe, and a patient who has had two is almost certain to have further trouble.

With early operation the prognosis is extremely good, death being rare after operation within 36 hours. Even when operation is undertaken later in the attack, the prognosis is still good unless general peritonitis has ensued, when the prognosis without operation is uniformly bad. A further great advantage of early operation is that drainage of the abdomen can usually be avoided, whereas in delayed operations drainage is frequently necessary.

Treatment—In patients with acute appendicitis operated upon within 36 hours of the onset the mortality rate in the hands of competent surgeons is negligible, and since it is quite impossible to determine the course which any particular attack is going to take, there can be no doubt that when the diagnosis is definitely established, operation should be undertaken at once. Some surgeons are of opinion that when the patient is seen later than 48 hours from the onset and is tending to improve, medical treatment should be undertaken until the attack has subsided and the appendix removed during the quiescent period. Since operation in such cases is, with competent surgery, very little more difficult or dangerous than in early cases such a view has little to recommend it since it condemns the patient to two tedious periods of sickness instead of one, and there is in addition the risk of the patient's natural objection to an operation when he feels perfectly well overcoming the advice he has been given and leaving him exposed to all the risks of a further attack. When peritonitis or localised abscess formation has occurred there are no two opinions as to the necessity of operation. If, for any reason operation is impossible or refused, the patient should be kept in the Fowler position should have nothing but water by mouth and may be given morphine to diminish both pain and intestinal movement, provided always that any question of operation has been finally and definitely decided. Chemotherapeutic and antibiotic agents should be administered. Under no circumstances should a purge be given as there can be no doubt that far too frequently purgation is the direct cause of perforation.

Where an appendicular abscess has developed it was formerly held that the abscess should be drained and the appendix removed subsequently. Modern surgical opinion is in favour of doing both at one operation and in the hands of an experienced operator this procedure is undoubtedly best, but where skilled surgical aid is not available simple incision and drainage of the abscess meet the immediate emergency.

SUBACUTE APPENDICITIS

Recurrent attacks of subacute appendicitis are not rare, but true chronic inflammation of the appendix, as such, does not occur. For this reason, though recurrent infection with subsequent fibrosis and adhesions may be diagnosed with some assurance the term chronic appendicitis should not be used.

Symptoms and Diagnosis—Many patients suffering from colon spasm, constipation or other abdominal symptoms have their appendix wrongly removed, either without benefit or with actual aggravation of their symptoms. Diffuse caecal tenderness is so frequent a finding on physical examination that its presence is alone of very little diagnostic significance. Pain localised to the right iliac fossa or in some cases of retro caecal or retro colic appendicitis to the right loin or right hypochondrium with localised tenderness on radiological examination may point to appendicular disease, in a few cases symptoms may simulate those of cholecystitis. In cases of recurrent appendicitis the symptoms are localised and not general, as in most neuroses, they may be made worse by physical exercise but are not relieved by food or alkalis. In rare cases, when the appendix is adherent to the rectum, there may be diarrhoea in the attacks. Nearly all cases of regional ileitis are at first misdiagnosed as chronic appendicitis as is often ileo caecal tuberculosis and carcinoma of the caecum.

Tuberculous mesenteric glands may also commonly cause local pain and tenderness in the right iliac fossa, usually with some persistent low fever and general ill health. A few patients suffering from duodenal ulcer symptoms seem to be lastingly relieved by removal of a fibrosed and adherent appendix, but any true causal relationship is uncertain. It is exceedingly doubtful if the "kinked", long or otherwise radiologically described "grumbling appendix" is ever the direct cause of indigestion or of digestive symptoms other than those indicated above.

DISEASES OF THE LIVER

The liver is our largest glandular organ, and is essential for life, since it is concerned with the main processes of nutrition. It is often referred to as the seat of intermediate metabolism, after absorption through the intestinal wall the main products of digestion are at once conveyed by the portal vein to the liver, where many elaborate activities involving disintegration and synthesis take place.

Most of the common named diseases of the liver (excluding abnormalities of growth and parasitic infestations) result from structural damage and such damage would usually be serious and more often fatal but for two facts which have a fundamental bearing on all aspects of liver diseases, and especially prognosis and treatment. 1 We possess a large supply of liver tissue in excess of our essential needs. It is well known that the greater part of the liver may be replaced by carcinoma and yet the functions of the organ remain for the time unimpaired. 2 The liver has remarkable powers of regeneration and repair. Not only do surviving cells rapidly regenerate, often to form large masses (nodular hyperplasia) but the new cells come into perfect alignment with a completely efficient system of bile ducts.

TESTS OF LIVER FUNCTION

The liver has so many functions that no single test can be expected to provide information about derangement of all of them. Moreover, the two facts already mentioned—the excess of liver tissue over normal requirements and the great capacity for repair—inevitably influence the results. On the whole the tests available demon-

strate disordered function readily in acute damage or disease, but do not tell what the clinician most wants to know, namely, the boundaries between adequate function and complete breakdown, especially in the more chronic diseases of the liver. In general the correlation between liver histology as shown by biopsy and the results of biochemical tests of function is not close, and gross pathological changes may be obvious under the microscope whilst functional tests remain normal. In practice it is unwise to rely on any one biochemical test alone, the most useful information being obtainable by a combined series of tests, if possible repeated over a period of time.

Liver biopsy—This technique was first described in 1895 and is now an accepted method of investigation. Various types of needle are used, and they may be inserted either below or just between the ribs, in the latter case the patient must co-operate by holding his breath. Good local anaesthesia is essential and the patient must remain in hospital for 12 hours after the test is completed. Among 10 000 biopsies the mortality was just over 0.1 per cent, and the incidence of complications 0.32 per cent. Liver biopsy is particularly useful in the diagnosis of chronic hepatitis, of hepatic enlargement of unknown nature, and as a guide to prognosis in cases of cirrhosis of the liver. It should not be performed in jaundiced patients unless the diagnosis remains uncertain after thorough physical and biochemical examination, as there is an increased risk of bleeding from the puncture in these patients. It may be of value in confirming a diagnosis of malignant metastases in the liver, sarcoidosis or of fatty infiltration. It demands considerable skill in its performance and should not be employed in cases where there are special risks of hæmorrhage.

The main biochemical tests of liver function are briefly described below.

I Tests based upon the formation and excretion of bile pigments *Van den Bergh Reaction Urobilinogen in Urine*—There are few hepatic diseases in which some increase in the bilirubin content of the blood does not result, and estimation of the serum bilirubin by the van den Bergh test or, more roughly, by the icterus index, may give evidence of disease even when clinical jaundice is absent. In general high values indicate severe liver damage but the converse is not necessarily true. Repeated examinations of blood bilirubin are often of great service in watching the waxing, waning and final recovery from disease. The amount of bilirubin in the plasma can be measured by a quantitative colour reaction, van den Bergh's test, which is given by Ehrlich's diazo reagent after adding alcohol. This test can detect variations in plasma level which are impossible to appreciate at the bedside. A sharp distinction was formerly drawn between reactions occurring before and after adding alcohol to the plasma, the "direct" and "indirect" reactions respectively, as it was believed that the former occurred only with obstructive jaundice and the latter with hæmolytic jaundice. It is now known that this is not consistently true, and as far as the differential diagnosis of most of the common forms of jaundice is concerned, the test is of little or no value.

Urobilinogenuria—Some of the bile which normally reaches the intestine, after conversion in the large intestine to stercobilinogen is excreted in the urine as the colourless urobilinogen, this oxidises in light and air to the bright yellow urobilin. Damage to the liver or excessive formation of bile pigments as in hæmolytic jaundice leads to increased amounts of urobilinogen in the urine, whereas complete obstruction of the bile duct prevents bile reaching the intestine and so prevents any urobilinogen appearing in the urine. The presence of urobilinogen is detected by Ehrlich's aldehyde reagent, which gives a bright pink colour when 0.5 ml is added to 5 ml of urine.

II Tests based on the part played by the liver in carbohydrate metabolism *Lævulose and Galactose Tolerance Tests*—Unfortunately pure lævulose is difficult to obtain and the test is so unreliable and of so little practical value that its use has been almost abandoned—the same is true also of the galactose test.

III. *Tests based on the detoxifying (toxiphylactic) function of the liver.* *Hippuric Acid Synthesis Test.*—Benzoic acid and its salts are conjugated in the liver with glycine to form hippuric acid which is excreted in the urine, and the test is carried out by giving sodium benzoate orally or intravenously. Renal disease, anæmia, pneumonia and other diseases invalidate the results of this test which is time-consuming, unreliable and of little value in diagnosis.

Bromsulphthalein Test.—This test is of no value in the presence of jaundice and depends upon the ability of the liver to remove the dye from the blood. It requires an intravenous dye injection with subsequent collection of a blood sample after 45 minutes. In normal subjects all the dye should by then have disappeared from the blood, whereas in cases of liver disease such as cirrhosis, there is continued dye retention.

IV. *Tests based on the activity of the liver in the manufacture of the plasma-proteins.*

(a) *Total serum proteins and albumin-globulin ratio.*—Accumulating evidence points to the liver as the site of origin of the albumin and part of the globulin of the plasma-proteins. Changes, and especially diminution, occur in many other diseases but when the liver is known to be involved they have a special significance. Experimental hepatic injury and both acute and chronic hepatitis in man lead almost constantly to a fall in albumin and a rise in globulin. In liver disease the normal figures for total plasma protein of approximately 7 to 8 g. per 100 ml. may be reduced to 5 or lower, and the normal figures for albumin and globulin of 4 to 5.5 g. per 100 ml., and 1.2 to 3 respectively are reversed so that the former may fall to 2 or lower and the latter rise to 5 or higher. In acute hepatitis these changes are slight or moderate, but they become extreme if subacute necrosis develops. In cases of cirrhosis these changes may also be marked, and there is, as a rule, a close relationship between the level of plasma albumin and the functioning capacity of the liver, so that it may be of help in assessing prognosis. Inversion of the albumin-globulin ratio persisting in a jaundiced patient is a serious indication of continuing hepato-cellular damage.

(b) *Cephalin Cholesterol Flocculation Test.*—This test was originally introduced by Hanger in America and depends on an alteration in the relative levels of the serum proteins. It is usually positive in cases of parenchymatous liver disease and is a useful aid in differentiating hepatic from obstructive jaundice.

(c) *Thymol Turbidity Test.*—This test is also dependent upon the globulin fractions in the serum and is performed by adding thymol to serum and recording the degree of flocculation (turbidity) observed. The result is recorded in units, the normal being 0 to 4. This test is rapid and simple to carry out, and is the most useful and sensitive of all the flocculation tests at present in use, values above 8 being strong evidence of hepato-cellular disease. It is not increased in cases of obstructive jaundice.

(d) Other flocculation tests less frequently used are the Takata Ara, colloidal gold and colloidal red tests. They have no advantages over the thymol turbidity test.

V. *Tests based upon Lipoid Metabolism.*—In obstructive jaundice there is usually a rise in the total blood cholesterol above the normal level of 120 to 250 mg. per 100 ml.; when such rise is not found in a jaundiced patient, the cause is usually hepato-cellular disease. Moreover, in liver disease, the percentage of cholesterol in esterified form, which is normally 50 to 70 per cent., falls and this reduction in cholesterol esters is roughly proportional to the degree of liver damage. The test is thus of value in estimating the extent of hepatic disease and state of recovery, if repeated estimations are carried out. Unfortunately, a number of complicating factors lessen the reliability of the test.

VI. *Serum Alkaline Phosphatase.*—This enzyme is excreted in the bile and in cases of obstructive jaundice its level in the blood is increased. The test is of value

in helping to differentiate obstructive from hepatic jaundice and in conjunction with other tests gives most useful information. Normal values lie between 3 to 13 King-Armstrong units, and levels below 30 units in the presence of jaundice almost always indicate a hepato-cellular rather than obstructive cause, whilst values above 40 units strongly suggest obstruction.

Summary.—In practice the most useful combination of biochemical tests is the estimation of serum proteins and albumin-globulin ratio, the alkaline phosphatase and thymol turbidity tests and of bilirubin in the blood. Valid conclusions can never be drawn from a solitary test, and if possible multiple tests repeated at intervals with due appreciation of their wide range of variability should be carried out. In conjunction with the clinical history and examination they may then be of real value, particularly in the differential diagnosis of cases of chronic jaundice.

JAUNDICE

Definition.—Jaundice is the condition caused by the presence of excess of bilirubin in the blood (bilirubinæmia) which manifests itself clinically by yellow colouration of the conjunctivæ and skin.

Ætiology and Pathology.—Many classifications of jaundice have been made, some of them based chiefly on ætiology and others on pathology. None of them is perfect, and for simple clinical purposes the best still appears to be a division into three groups, hæmolytic jaundice, toxic and infective hepatic jaundice and obstructive jaundice.

(a) **HÆMOLYTIC JAUNDICE.**—In hæmolytic jaundice bilirubin is produced in excess from hæmoglobin set free in the circulation by the destruction of red cells as a result of abnormal fragility, as in acholuric jaundice, or of the presence of hæmolytic toxins in the blood. The hæmoglobin is broken down in cells of the reticulo-endothelial system in the spleen, bone-marrow and elsewhere, and the bilirubin is carried to the liver for excretion. The excess of bile-pigment is thus formed quite independently of the glandular cells of the liver, and the condition is often referred to as a "dis-sociated jaundice".

(b) **TOXIC AND INFECTIVE JAUNDICE.**—This is by far the commonest variety, and is the result of damage or necrosis of liver cells which are unable completely to transfer the pigment from the blood to the bile-capillaries. Some pigment is therefore retained in the blood, but some passes through for excretion in amount depending on the extent of the damage and the stage of repair. Further, the bile-pigment which reaches the bile-ducts may again be obstructed (see below) by cholangitis. In this variety of jaundice therefore the excessive bile-pigment in the blood may be of two kinds—one which has passed through the glandular cells of the liver and one which has not done so.

(c) **OBSTRUCTIVE JAUNDICE.**—In obstructive jaundice bile excreted by the hepatic cells is reabsorbed by the hepatic blood capillaries, together perhaps with the lymphatics, owing to the rise in pressure caused by obstruction of the bile-ducts. The obstruction may occur (1) within the ducts, or it may be due to (2) changes in their walls or (3) pressure from without.

1. **Obstruction within the ducts.**—This is almost always due to gall-stones. In very rare cases a hydatid cyst ruptures into a duct, which becomes obstructed by a piece of membrane or a daughter cyst, or a round worm enters the common bile-duct from the duodenum.

2. **Obstruction due to changes in the walls of the ducts.**—Congenital obliteration of the bile-ducts is a rare cause of simple jaundice in infants (p. 699). An acquired stricture may result from accidental injury of the common-bile-duct during operation. Infective and suppurative cholangitis lead to jaundice, but in some cases the obstruc-

tion to the ducts is associated with changes in the liver cells, which are in part responsible for the production of the jaundice. Jaundice is an early symptom of primary carcinoma of the hepatic and common bile ducts and biliary papilla.

3 *Pressure on the ducts from without*—Carcinoma of the liver and very rarely gummata and hydatid cysts give rise to jaundice by pressing on the intrahepatic branches of the bile ducts, if some of the latter escape, bile still passes into the duodenum from other parts of the liver and the faeces remain coloured. The tumour may also project into the portal fissure and give rise to jaundice with colourless stools by pressing upon the hepatic ducts or common bile duct.

Enlarged glands in the portal fissure may cause jaundice by pressure upon the ducts. The most common cause is primary or secondary cancer of the liver, as these glands drain the liver, but not the other abdominal viscera or peritoneum, for the same reason they rarely become tuberculous. They are very rarely enlarged in Hodgkin's disease and glandular fever and never in syphilis.

Jaundice may occur in cancer of the stomach, even when no secondary deposits are present in the liver or in the glands in the portal fissure. This is due to the pressure of glands in the neighbourhood of the head of the pancreas, or to direct spread of the growth into the lesser omentum, where it compresses the common bile duct and may invade its walls.

Jaundice is produced by obstruction of the common bile duct when chronic pancreatitis occurs in an individual in whom the duct is embedded in the head of the gland. It is generally present in cancer of the head of the pancreas, but very rarely with a pancreatic cyst or calculus.

(d) **LATENT JAUNDICE**—The recognition that bilirubin is always present in the blood and the development of tests such as the van den Bergh reaction, by which fairly accurate quantitative measurements can be made, have shown the existence of latent jaundice. This is important in a variety of hepatic diseases and also in other conditions such as pernicious anaemia. Normally the bilirubin content of the blood is about 1 in 250,000 (0.4 mg per 100 ml) and except in hæmolytic jaundice the concentration must rise to 1 in 50,000 (2 mg per 100 ml) before bile pigment appears in the urine and the skin begins to be coloured.

In hæmolytic (or dissociated) jaundice, on the other hand, the renal threshold is much higher, and no bile pigment may be found in the urine in spite of a concentration greatly exceeding the normal in the blood.

Symptoms—Jaundice appears first in the conjunctivæ and then successively on the face, neck, body and limbs. The mucous membrane of the lips and palate becomes yellow very soon after the conjunctivæ. In chronic obstructive jaundice the pigment in the skin becomes dark green. In a small proportion of very chronic cases xanthoma develops but this condition is more common without jaundice (p. 784). The patches consist of cholesterol which the blood in jaundice contains in excess. In chronic jaundice there is a tendency for telangiectases to develop over the body and face, they may disappear at the same time as the jaundice. Purpura and hæmorrhage from mucous membranes, especially the nose and gums may occur as a result of deficiency in vitamin K.

The urine becomes bile stained before the conjunctivæ and skin, the interval being sometimes as long as 24 hours but it generally returns to normal before the yellow colour of the skin has disappeared. The urine may be yellow, olive, dark brown or even black. The colour can be distinguished from that in urobilinuria, hæmaturia and melanuria, and that produced by rhubarb, senna, santonin and chrysophanic acid by Gmelin's test for bile pigment.

When obstruction to the bile ducts is complete, no bile reaches the intestines and urobilin is absent from the urine, when the obstruction is incomplete, decomposition of the bile which reaches the intestines may occur and urobilinuria results. Bile-salts are present in the urine only for the first few days. Their dis-

appearance is due to the fact that they are produced in very small quantities, being constantly reabsorbed from the bowel and re-excreted, when the bile-ducts are obstructed the kidneys rapidly excrete all the bile-salts present in the blood. In chronic obstructive jaundice bile stained casts are almost always present in the urine, and less frequently albuminuria occurs. The urine may reduce Fehling's solution owing to the presence of glycuronic acid.

The faeces are bulky and often extremely offensive. When the obstruction is complete they are clay-coloured, owing partly to the absence of stercobilin and partly to the presence of excess of fatty acids and soaps, which require the presence of bile for their complete absorption, and of neutral fat if the pancreatic duct is simultaneously obstructed (p 701). Loss of weight results, and the excess of undigested food which reaches the colon is likely to cause excessive bacterial decomposition. This may lead to intestinal symptoms and toxæmia if the hepatic cells are damaged and their detoxifying action impaired.

The sweat may contain bile, which is also sometimes present in the tears and in the milk, but the saliva, cerebrospinal fluid and mucus of the alimentary canal are free from bile, although the salivary glands and other organs are deeply bile stained. The sputum in pneumonia and the effusion in pleurisy and peritonitis contain bile-pigments. The blood plasma is tinged with bile. Coagulation is considerably delayed in obstructive jaundice owing to deficiency of prothrombin. This is a result of lack of fat-soluble vitamin K ("Koagulation vitamin"), too little of which is absorbed when bile is absent from the small intestine.

In jaundice of recent origin the pulse may be slow as a result of the presence of bile salts in the blood. Pruritus occurs in about 20 per cent of cases, especially when the jaundice is deep, it may be very severe and interfere with sleep. It is not directly due to the jaundice, as it may develop several days before the jaundice appears and continue after its disappearance. When present before the jaundice, it may subside with the onset of the latter. It may also disappear at a time when the jaundice is still as intense as ever. It is most frequently seen in obstructive cases.

The yellow vision or xanthopsia of jaundiced patients is less marked than that caused by santonin, and is rarely sufficiently obvious for the patient to mention it unless directly asked.

Diagnosis—The importance of latent jaundice has already been referred to, but even when the conjunctivæ and skin are already yellow the diagnosis of jaundice may be completely missed if the patient is only seen in artificial light. This clinical point cannot be over-emphasised.

1 Age, sex and history—Transient jaundice is common in the newly born (p 746). Obstructive jaundice may result from congenital obliteration of the bile-ducts (p 699) and congenital syphilis (p 681). Severe jaundice in infants may be familial (p 745). Mild infective jaundice may occur sporadically or in epidemics among infants, it is identical with the infective hepatitis of older children and adults.

Jaundice occurring in childhood or before the age of 30 is generally caused by infective hepatitis. After 30, gall stones become a more common cause, especially in women, and after 40 cancer is the most common cause in both sexes. Jaundice developing in pregnancy should raise a suspicion of acute necrosis of the liver. When two or more members of a family are affected, an infective hepatitis, leptospiral jaundice or a toxæmia is the cause in acute cases. In chronic cases acholuric jaundice is probably present.

In jaundice of obscure origin the possibility of a toxic cause should be remembered, and enquiries made whether the patient has recently received treatment with organic arsenical preparations, Atophan or other hepatic poison. Serum jaundice (p 666) is clinically indistinguishable from infective hepatitis except by the history of a probable cause at the material time interval previously. Most cases of so-called arsenical jaundice are due to faulty sterilisation of syringes which have been contamin-

ated with traces of blood containing the ierogenic agent and not to the arsenic itself

2 Colour—In hæmolytic anæmia the skin has a characteristic lemon-yellow colour, though the conjunctivæ may be unaffected. In acute and subacute hepatic necrosis, such as the toxic jaundice caused by arsenobenzene, the skin assumes a very bright yellow colour, which is quite distinct from that of the jaundice caused by obstruction of the bile passages. A dirty or greenish yellow colour occurs only in chronic and more or less complete obstructive jaundice.

3 Course—Jaundice of very short duration is generally due to the passage of a gall stone. If it lasts some days infective hepatitis is equally probable. Obstructive jaundice, which progresses until it becomes extremely deep, suggests cancer, whilst chronic jaundice, which varies from time to time, and intermittent jaundice are generally due to a stone in the ampulla of the bile-duct, but may also be due to cancer of the ampulla.

4 Condition of the gall bladder—Enlargement of the gall bladder indicates obstruction of the cystic or common bile duct, though the former is not likely to be associated with jaundice. The enlargement is present in over 90 per cent. of cases in which obstruction is due to causes other than gall stones, but in only 20 per cent. of cases of calculous obstruction. The difference is due to the contraction of the gall bladder caused by chronic inflammation in cholelithiasis, in which, moreover, the obstruction is often incomplete. This is known as Courvoisier's law, but as it has 20 per cent. exceptions it is no law, as Courvoisier (1890) well knew.

5 Condition of the liver—Jaundice associated with great enlargement of the liver is generally due to growth if it is irregular, and to chronic obstruction of the common bile duct if the liver is smooth, the irregular enlargement due to syphilis is less extreme, and, like that due to hydatid cysts or an abscess, is rarely associated with jaundice. The presence of ascites points to a growth or to cirrhosis, but the jaundice is generally greater in the former.

6 Examination of the stools—The presence or absence of stercobilin in the stools shows whether the common bile duct is incompletely or completely obstructed. Slight excess of fatty acid and soap without any striated meat fibres or starch occurs in uncomplicated jaundice, excess of neutral fat, as well as fatty acid and soap together with striated meat fibres points to obstruction of the pancreatic duct. Complete absence of both bile and pancreatic juice from the intestinal contents indicates obstruction at the ampulla of Vater.

7 Pain—Constant pain suggests growth or, at the onset, infective hepatitis attacks of pain gall stones and absence of pain acute or subacute necrosis. Many exceptions to this general statement occur. Chronic pancreatitis may be painless as may carcinoma of the pancreas, but more usually pain is present, often of severe degree.

8 Syphilis—Active signs of syphilis or scars of old lesions indicate the possibility of a syphilitic origin, or of infection through an arsenical injection which a patient may be having for syphilis without his own doctor's knowledge.

Treatment—The treatment of jaundice is the treatment of the condition which causes it. The subject, therefore, requires no further consideration here, except for the pruritus and tendency to hæmorrhage, which are results of the jaundice itself. Thyroid gr $\frac{1}{2}$ three times a day, and fractional doses of calomel may give relief to the pruritus which is also helped by a warm alkaline bath, or moistening the irritable parts of the skin with 1 in 40 carbolic acid, 1 in 50 ichthammol, or 1 in 70 solution of menthol in spirit. Sedatives should be used with caution in liver disease and especially the barbitones and opium derivatives, but if sleep is much interfered with paraldehyde 3 to 10 ml intramuscularly is safe and often successful. The anti-histamine drugs are also of value in controlling the itching and should be tried in full dosage especially at night.

Vitamin A—This vitamin has been prepared from alfalfa cereals and other sub

stances, as well as a number of synthetic analogues under the names menaphthone (B P) and menadione (U S P). Vitamin K causes a rapid rise in plasma prothrombin and is thus able to control considerably the hæmorrhagic tendency present in many cases of obstructive jaundice. When given by mouth it must be combined with bile salts (or it is not fully absorbed), and a dose of 5 to 10 mg daily with gr 5 of bile salts is sufficient to raise the prothrombin level to normal in 12 to 36 hours. Intramuscular injections of the synthetic products dissolved in oil are painful but act more certainly and more rapidly. Intravenous injections can also be given. Vitamin K should always be administered before an operation on any patient with obstructive jaundice, preparations such as Kapon, Synkavit (water-soluble) being suitable in doses of 10 mg. Also see p 769.

CHRONIC INTERMITTENT JUVENILE JAUNDICE

A number of writers have described a condition, seen predominantly in men between the ages of 15 and 25, in which intermittent periods of lassitude and jaundice occur over many years, and in which an hereditary basis can often be detected.

Ætiology and Pathology—No definite cause is known but, as stated, an hereditary factor is often present, and attacks are especially brought on by external factors, such as alcohol, lack of sleep, overwork and mental anxiety. Liver biopsy has shown only slight fatty infiltration of the liver cells but no inflammatory changes or evidence of cirrhosis. Liver function tests are usually normal.

Symptoms—Periodic lassitude, with slight jaundice and sometimes mild dyspeptic symptoms are the only complaints. There is never itching, and the yellow staining of the sclerotics is only faint, if in fact it is detected at all. The serum bilirubin is raised but fluctuates considerably, values between the normal and 35 for the icterus index being found at different times. The urine is normal in colour and bile pigments are not present.

Diagnosis—The condition may be suspected in any case of a young adult showing barely detectable jaundice, varying in intensity but continuing for many years with periodic bouts of fatigue, but the malady can only be diagnosed for certain with the aid of the serum bilirubin estimation. There is no enlargement or tenderness of the liver, as occurs in infective hepatitis, and no signs of hæmolytic, or splenic enlargement as occurs in chronic hereditary hæmolytic jaundice.

Prognosis and Treatment—The prognosis is uniformly good. As Meulengracht has written, the most important therapy that can be given is the diagnosis. No special dietetic or medicinal treatment is indicated.

HÆMOLYTIC DISEASE OF THE NEWBORN (see p 745)

ACHOLURIC JAUNDICE (see p 741)

CONGESTION OF THE LIVER

Ætiology—When the outflow of blood from the hepatic vein is impeded as a result of right sided heart failure, following primary disease of the heart or obstructive pulmonary disease such as emphysema, passive congestion of the liver may result. It is also produced by thrombosis of the hepatic veins, a rare condition generally secondary to some neighbouring malignant, syphilitic or inflammatory disease.

Pathology—The sublobular and intralobular veins are dilated. The centre of each lobule thus appears as a dark spot, whilst the outer part is pale owing to fatty infiltration. The mottled appearance resembles the section of a nutmeg and has led to the name "nutmeg liver".

Symptoms—In addition to the symptoms of the cardiac or pulmonary disease,

which has led to the right-sided heart failure, special symptoms result from the passive congestion of the liver. The capsule of the liver is stretched and pain results, especially if the enlargement is rapid. When the increase in size is more gradual, there is a feeling of fullness and weight in the right hypochondrium. The liver can be felt to extend considerably lower than normal, its size varying from time to time according to the condition of the heart. It is firm and tender, especially if the congestion is recent and acute. Distinct expansile pulsation can sometimes be felt by placing one hand in the loin and the other just below the right costal margin; which corresponds with ventricular systole if tricuspid regurgitation exists. It must be distinguished from the non-expansile pulsation transmitted through the diaphragm from the labouring right ventricle.

The congestion of the liver leads in turn to congestion of the organs which are drained by the portal vein. Anorexia, discomfort immediately after food, flatulent distension of both stomach and intestines from deficient absorption of the gas swallowed with the food or produced by fermentation, and constipation are commonly present. The combination of slight jaundice with cyanosis produces a characteristic dusky colour of the face. The jaundice is, however, often latent, a positive van den Bergh reaction being obtained with no pigmentation of the skin or conjunctivæ.

Ascites is common, but is rare in the absence of general œdema, being mainly due to the same causes; it is also in part a direct result of portal congestion and sometimes of chronic peritonitis. The spleen is very rarely enlarged in spite of the interference with the outflow of blood in the splenic vein by the hepatic congestion.

Diagnosis.—When cardiac or pulmonary disease is obvious, the diagnosis is easy. Sometimes, however, the most prominent symptoms are due to the congestion of the liver, and the diagnosis from cirrhosis may be difficult. In congestion of the liver the spleen is not enlarged, and the symptoms rapidly improve and the liver diminishes in size with rest and cardiac treatment. Moreover, hæmatemesis, though common in cirrhosis, very rarely occurs in passive congestion in spite of the engorgement of the gastric mucous membrane.

Treatment.—Diet has no effect on the flatulence, which can only be relieved by treatment of the cardiac condition. Digitalis and mercurial diuretics will do more to reduce hepatic pain and discomfort than any local application, but in some cases venesection may do good. Mild purgation with magnesium sulphate may also help to relieve the portal congestion.

INFECTIVE HEPATITIS

Infective hepatitis, which was formerly designated catarrhal jaundice, has become increasingly common in the last 15 years, both in Great Britain and abroad, and in the War of 1939–1945 it was the most important infection in the British Army in Africa, the Near East and India.

Ætiology and Pathogenesis.—Data at present available show that an icterogenic agent is present in the blood-stream in cases of hepatitis, and may exist there before symptoms arise and before any evidence of liver damage can be detected. This agent is now known to be a living virus, and healthy volunteers given dried Seitz filtered extracts of urine and stools from jaundiced patients have developed hepatitis both when extracts were given orally and intra-nasally. Naso-pharyngeal washings taken from cases of hepatitis, however, have so far not been shown to transmit the disease, and there is at present no test known which will detect the presence of the icterogenic agent except observation of the result of transmission to man; no method of culture *in vitro* has yet been successful.

Homologous Serum Hepatitis.—Much of our knowledge of the causation of infective hepatitis has come through a study of the very closely allied, but almost certainly

not identical condition now generally entitled homologous serum jaundice, though more correctly it should be known as homologous serum hepatitis. Experimental work on this condition has shown that the causative agent will pass through filters which retain bacteria, is extremely resistant to heat and disinfectants, surviving storage at low temperatures for very long periods, and is probably very similar though not identical with that which causes natural infective hepatitis. Serum hepatitis differs from infective hepatitis in having an incubation period of between 60 and 150 days, and in having an appreciably higher mortality, even though the majority of the cases are mild.

Serum hepatitis may follow the transfusion of whole blood, serum or plasma, it has resulted from the injection of convalescent human serum used in the prophylaxis of measles and mumps, it occurs after the use of syringes contaminated by human blood and in this way accounts for cases of so called post-arsphenamine jaundice, cases of "post-vaccinal jaundice" have followed the use of yellow fever and other vaccines, and in 1941 one series of yellow fever vaccines was responsible for over 23,000 cases in the U.S. Army with an incidence of over 5 cases per 100 doses of vaccine.

Post transfusion jaundice was of serious importance during the War of 1939-1945, and in 1945 was for a time a major cause of death in U.S. hospitals in England, an incidence of 7.3 per cent of cases of jaundice following transfusion with pooled serum or plasma was reported in 1946 among 2,040 patients transfused. In some series the mortality has been as high as 12 per cent. Experimentally the intensity of the hepatitis has shown no relationship to the amount of dried serum injected—as little as 0.1 ml. intravenously being enough to cause severe hepatitis, even of a serum stored for over 2 years.

Epidemiology—Infective hepatitis most frequently affects those under 40 years of age. The main epidemics occur in the autumn, but sporadic cases are found at all times of the year. The incubation period is between 15 and 35 days and the mode of infection is both through stools and urine, and probably by air borne droplets from the saliva and naso-pharyngeal secretions. The pre-icteric stage is said to be the most infective period but there is some evidence that the blood may remain infective for a considerable time after jaundice has actually disappeared. It is quite rare for cases to develop hepatitis from bed to bed contact unless sanitation is defective, and it is not essential to isolate the patient provided ordinary precautions are taken as for other excremental diseases. It is probable that cases may arise through careless contamination of food or drink with excreta of individuals in a household suffering from apparently simple gastro-enteritis without jaundice.

During the War of 1939-1945 the incidence was markedly higher amongst officers than amongst men, a fact which has been attributed by some to the immunity developed by the men owing to the repeated minor infections which they suffer and from which the officers are more protected owing to their better hygiene and feeding arrangements.

Morbid Anatomy—Post-mortem examination in the numerous fatal cases occurring in the extensive epidemic in Scandinavia in 1926 and 1927, and in epidemics in Great Britain and in the British Army overseas in 1942 and 1943 always showed acute or subacute hepatic necrosis. Liver biopsy has demonstrated that the primary change is inflammatory, and that the necrosis is to a large extent the result of post-mortem autolysis. Inflammatory changes are invariably present in the connective tissue, the parenchyma shows irregular foci of necrosis and glycogen disappears from the cells. The lobular pattern is lost. With the disappearance of symptoms the inflammatory cells rapidly disappear and the lobular pattern is restored. The jaundice is in part a result of impaired functional activity of the hepatic cells, which normally take up the bile pigment from the undamaged reticulo-endothelial cells, and excrete them into the bile capillaries, and in part a result of disorganisation of the structure

which has led to the right-sided heart failure, special symptoms result from the passive congestion of the liver. The capsule of the liver is stretched and pain results, especially if the enlargement is rapid. When the increase in size is more gradual, there is a feeling of fullness and weight in the right hypochondrium. The liver can be felt to extend considerably lower than normal, its size varying from time to time according to the condition of the heart. It is firm and tender, especially if the congestion is recent and acute. Distinct expansile pulsation can sometimes be felt by placing one hand in the loin and the other just below the right costal margin; which corresponds with ventricular systole if tricuspid regurgitation exists. It must be distinguished from the non expansile pulsation transmitted through the diaphragm from the labouring right ventricle.

The congestion of the liver leads in turn to congestion of the organs which are drained by the portal vein. Anorexia, discomfort immediately after food, flatulent distension of both stomach and intestines from deficient absorption of the gas swallowed with the food or produced by fermentation, and constipation are commonly present. The combination of slight jaundice with cyanosis produces a characteristic dusky colour of the face. The jaundice is, however, often latent, a positive van den Bergh reaction being obtained with no pigmentation of the skin or conjunctivæ.

Ascites is common, but is rare in the absence of general œdema, being mainly due to the same causes, it is also in part a direct result of portal congestion and sometimes of chronic peritonitis. The spleen is very rarely enlarged in spite of the interference with the outflow of blood in the splenic vein by the hepatic congestion.

Diagnosis.—When cardiac or pulmonary disease is obvious, the diagnosis is easy. Sometimes, however, the most prominent symptoms are due to the congestion of the liver, and the diagnosis from cirrhosis may be difficult. In congestion of the liver the spleen is not enlarged, and the symptoms rapidly improve and the liver diminishes in size with rest and cardiac treatment. Moreover, hæmatemesis, though common in cirrhosis, very rarely occurs in passive congestion in spite of the engorgement of the gastric mucous membrane.

Treatment.—Diet has no effect on the flatulence, which can only be relieved by treatment of the cardiac condition. Digitalis and mercurial diuretics will do more to reduce hepatic pain and discomfort than any local application, but in some cases venesection may do good. Mild purgation with magnesium sulphate may also help to relieve the portal congestion.

INFECTIVE HEPATITIS

Infective hepatitis, which was formerly designated catarrhal jaundice, has become increasingly common in the last 15 years, both in Great Britain and abroad and in the War of 1939-1945 it was the most important infection in the British Army in Africa, the Near East and India.

Ætiology and Pathogenesis.—Data at present available show that an ieterogenic agent is present in the blood stream in cases of hepatitis, and may exist there before symptoms arise and before any evidence of liver damage can be detected. This agent is now known to be a living virus, and healthy volunteers given dried Seitz filtered extracts of urine and stools from jaundiced patients have developed hepatitis both when extracts were given orally and intra nasally. Naso pharyngeal washings taken from cases of hepatitis however, have so far not been shown to transmit the disease, and there is at present no test known which will detect the presence of the ieterogenic agent except observation of the result of transmission to man, no method of culture *in vitro* has yet been successful.

Homologous Serum Hepatitis.—Much of our knowledge of the causation of infective hepatitis has come through a study of the very closely allied, but almost certainly

not identical condition now generally entitled homologous serum jaundice, though more correctly it should be known as homologous serum hepatitis. Experimental work on this condition has shown that the causative agent will pass through filters which retain bacteria, is extremely resistant to heat and disinfectants, surviving storage at low temperatures for very long periods, and is probably very similar though not identical with that which causes natural infective hepatitis. Serum hepatitis differs from infective hepatitis in having an incubation period of between 60 and 150 days, and in having an appreciably higher mortality, even though the majority of the cases are mild.

Serum hepatitis may follow the transfusion of whole blood, serum or plasma; it has resulted from the injection of convalescent human serum used in the prophylaxis of measles and mumps; it occurs after the use of syringes contaminated by human blood and in this way accounts for cases of so-called post-arsphenamine jaundice; cases of "post-vaccinal jaundice" have followed the use of yellow fever and other vaccines, and in 1941 one series of yellow fever vaccines was responsible for over 23,000 cases in the U.S. Army with an incidence of over 5 cases per 100 doses of vaccine.

Post-transfusion jaundice was of serious importance during the War of 1939-1945, and in 1945 was for a time a major cause of death in U.S. hospitals in England; an incidence of 7.3 per cent. of cases of jaundice following transfusion with pooled serum or plasma was reported in 1946 among 2,040 patients transfused. In some series the mortality has been as high as 12 per cent. Experimentally the intensity of the hepatitis has shown no relationship to the amount of dried serum injected—as little as 0.1 ml. intravenously being enough to cause severe hepatitis, even of a serum stored for over 2 years.

Epidemiology.—Infective hepatitis most frequently affects those under 40 years of age. The main epidemics occur in the autumn, but sporadic cases are found at all times of the year. The incubation period is between 15 and 35 days and the mode of infection is both through stools and urine, and probably by air-borne droplets from the saliva and naso-pharyngeal secretions. The pre-icteric stage is said to be the most infective period but there is some evidence that the blood may remain infective for a considerable time after jaundice has actually disappeared. It is quite rare for cases to develop hepatitis from bed to bed contact unless sanitation is defective, and it is not essential to isolate the patient provided ordinary precautions are taken as for other excremental diseases. It is probable that cases may arise through careless contamination of food or drink with excreta of individuals in a household suffering from apparently simple gastro-enteritis without jaundice.

During the War of 1939-1945 the incidence was markedly higher amongst officers than amongst men, a fact which has been attributed by some to the immunity developed by the men owing to the repeated minor infections which they suffer and from which the officers are more protected owing to their better hygiene and feeding arrangements.

Morbid Anatomy.—Post-mortem examination in the numerous fatal cases occurring in the extensive epidemic in Scandinavia in 1926 and 1927, and in epidemics in Great Britain and in the British Army overseas in 1942 and 1943 always showed acute or subacute hepatic necrosis. Liver biopsy has demonstrated that the primary change is inflammatory, and that the necrosis is to a large extent the result of post-mortem autolysis. Inflammatory changes are invariably present in the connective tissue, the parenchyma shows irregular foci of necrosis and glycogen disappears from the cells. The lobular pattern is lost. With the disappearance of symptoms the inflammatory cells rapidly disappear and the lobular pattern is restored. The jaundice is in part a result of impaired functional activity of the hepatic cells, which normally take up the bile pigment from the undamaged reticulo-endothelial cells, and excrete them into the bile capillaries, and in part a result of disorganisation of the structure

of the lobules with consequent rupture of the intralobular bile capillaries. The interlobular and larger bile-ducts are unaffected, and the stomach and duodenum are normal. The pathological appearance of the liver in homologous serum hepatitis is indistinguishable from that found in hepatitis, and fatal cases show a massive hepatic necrosis.

Symptoms.—In all but a few mild cases jaundice is preceded by other symptoms. The mode of onset is usually very characteristic but certain other variable types may be described.

Most commonly there is a gradual onset over several days of severe anorexia, nausea, constipation and headache. Vomiting is often present but is less frequent than the almost continuous feeling of nausea, especially marked at any smell, sight or even thought of food. Epigastric discomfort is present in most cases, occasionally amounting to quite severe pain, but never colicky as in gall-stone attacks. Some pyrexia occurs during this pre-icteric period, which averages 3 to 4 days but may vary from 24 hours to 15 days or even longer. As soon as jaundice appears the symptoms and fever usually quickly improve, and appetite often returns with remarkable rapidity.

In about 20 per cent. of cases the onset is violent and sudden, resembling severe influenza, malaria or even meningitis; the temperature may rise to 105° F. with rigors, intense headache, general pains and prostration. The temperature may remain high for several days but jaundice often does not develop in these cases until the fifth or sixth day of the illness. Paradoxically such severe cases at the onset often recover exceptionally quickly and have a particularly good prognosis, perhaps partly because they are, as a rule, treated urgently and at once in bed when milder cases are not.

In a proportion of mild ambulatory cases, perhaps 10 to 30 per cent., there are no symptoms whatever of ill health and the only abnormality noticed is an icteric tinge in the eyes and skin. Jaundice is not deep and appetite is not impaired. In another group a mild coryzal illness, or a slight febrile "bilious attack" with vomiting, headache and vague abdominal discomfort occurs but no clinical jaundice ever develops. Such cases are not rare in epidemics of infective hepatitis and should always be borne in mind in such circumstances. It is probable that ambulatory non-icteric cases are an important cause of spread of infection, resembling in this way the non-paralytic cases of anterior poliomyelitis. Diagnosis of the mild sporadic cases is difficult and may be impossible, but in an epidemic, if this type of case is remembered the symptoms together with slight enlargement of the liver and sometimes a transient trace of bile in the urine should enable a fairly confident opinion to be given.

Pruritus is rare in cases of infective hepatitis, but *general depression is common* and considerable loss of weight and weakness may follow any but the mild cases. Dehydration may be pronounced at the onset if vomiting is at all severe. Mental symptoms are unusual except as a premonitory sign of beginning hepatic necrosis (*q.v.*) when delirium, mania, convulsions or coma may occur. On examination the jaundice may be very deep or only just detectable as a faint yellow tinge in the sclerotics. The pulse is often slow, 50 to 60, but this is by no means a constant sign or of much help in diagnosis, being usually rapid during the pyrexial period and tending to become slower at the later stage of the disease. The liver is almost always palpable, being in some cases much enlarged. Such enlargement may considerably precede the appearance of jaundice, and does not run parallel by any means to its intensity, persisting often for some time, after all signs of jaundice have disappeared. The liver is smooth, tender and firm but not hard; the lower edge may reach as low as the umbilicus, but in more than half the cases is only one or two finger-breadths below the costal margin, in about one-third of the cases it is not palpable at all. The spleen is slightly enlarged in less than one-fifth of the cases.

The bilirubin in the serum is increased above the normal value of 0.4 mg per cent to values between 2 and 40 mg per cent, such excess often remaining in the blood for some time after apparent clinical recovery. The blood count may be normal but more usually shows a relative lymphocytosis with some leucopenia, leucocytosis does not occur, and there is no anaemia.

Diagnosis—The diagnosis in the pre-icteric period is suggested by the characteristic triad of anorexia, nausea and fever. In older patients the distinction from jaundice due to carcinoma of the pancreas may be extremely difficult, but any severe pruritus should always arouse a suspicion of an obstructive jaundice due to growth or stone. Liver function tests are of some help in the differential diagnosis, and a markedly positive thymol turbidity test is very suggestive of hepatitis rather than a duct obstruction. The serum bilirubin is rarely raised until immediately before jaundice appears. No specific laboratory test for hepatitis has yet been discovered. Regular estimations of serum bilirubin are of considerable value in judging the progress of a case, and so helping in the distinction between obstructive malignant disease and severe hepatitis.

The possibility of Weil's disease must be remembered, and the presence of albuminuria together with positive serological tests (*q.v.*) will confirm the diagnosis.

Prognosis—The average total duration of the illness is from 20 to 40 days but in a number of patients a so-called 'post-hepatitis syndrome' characterised by fatigue, anorexia, dyspepsia and a palpable liver may persist for many weeks, making convalescence very slow. These symptoms are in many cases psychogenic, and liver biopsies have not shown evidence of cirrhosis or other histological changes in the liver. Depression and intolerance to alcohol and fatty food are commonly noticed for a time after recovery. In others, however, the disease appears to remain active and a condition of chronic hepatitis with progressive liver cell degeneration and fibrosis results. Hepatic necrosis at the time of an attack may also later lead to cirrhosis of the liver with nodular hyperplasia and scarring. Such sequelae, though fortunately rare, are of very great importance and are particularly likely to occur in individuals who have lived on diets deficient in protein before acquiring hepatitis.

The mortality is low amongst healthy well-fed individuals, being not more than 1 or 2 per thousand, though varying somewhat in different epidemics, amongst undernourished or debilitated people, however, it may rise to 2 or 3 per cent.

Relapses occur in from 2 to 8 per cent. of cases and are usually mild, coming on from 3 to 6 weeks after recovery from the initial illness. Alcohol may undoubtedly precipitate such relapse and also may appear to bring on jaundice in a patient incubating the disease. Second attacks though infrequent are by no means as rare as is generally believed, and exceptionally three or even more attacks at intervals apart may occur in the same patient.

Treatment—**PREVENTION**—The chief means of prevention lie in attention to personal hygiene and general sanitation. Care in washing and in the handling of food is especially essential during an epidemic and by those in contact with cases of supposed gastro-enteritis or undiagnosed fever. The use of gamma globulin in a dose as low as 0.01 ml per pound body weight injected intramuscularly has seemed to produce immunity which has lasted several months or longer; some trials have suggested that this may be partly an active response conferring more than merely a temporary passive protection. Previous good nutrition and an adequate protein intake are almost certainly of importance in lessening the severity of an attack. During an attack patients should be kept completely in bed in the course of the earlier stages and as a rule, it is wise to continue this until the jaundice has disappeared. If, however, the patient has no symptoms, feels well and is eating a full diet he may be allowed up in his room even though slight jaundice is still present, but this should rarely be allowed under 2 weeks from the onset of the illness. If the patient is able to eat normally, the diet should not be restricted and carbohydrates and proteins

especially should be given freely from the start. This is in order to maintain the glycogen deposits in the liver cells (carbohydrates) and the plasma proteins which are often lowered in liver disease (proteins). A low fat diet has no special merit, and fats need not be avoided unless they cause nausea and vomiting, or are so repugnant that the patient feels unable to eat them. If there is much vomiting it is essential to ensure that adequate fluid and glucose are given, either rectally or intravenously, and it is wiser to give 1 or 2 litres of glucose saline intravenously early than to wait until the patient shows signs of dehydration. As a rule sweet drinks containing glucose, jellies, biscuits, boiled sweets and stewed fruit with sugar are well taken, and iced skimmed milk is often tolerated well. The administration of amino acids—cysteine and methionine—by mouth in doses of 3 to 5 g daily have in some cases appeared to shorten the duration of the illness, but their use on the whole has proved disappointing.

The use of ascorbic acid, 100 mg daily, and of vitamin K is advisable if any operative interference is needed during the illness or if any signs of hæmorrhage such as purpura occur. Drugs have no place in treatment, except symptomatically, but some benefit has been reported from the use of chlortetracycline. Aspirin may be given safely for headache, and various dyspeptic mixtures may be tried for the nausea and vomiting, rhubarb and soda sometimes seeming to act satisfactorily. Morphine is contraindicated in cases of hepatitis, and even the barbitones in small doses, e.g. phenobarbitone, gr $\frac{1}{2}$ two or three times a day, should only be ordered if there is very severe insomnia or itching.

During convalescence the avoidance of chilling is important and alcohol should be forbidden for several weeks or longer after recovery, according to the severity of the illness. In some cases alcohol tolerance is lowered for a long time, or even permanently, and strict teetotalism may be advisable. Signs of drowsiness, mental confusion, delusions or mania, or of reduction in the urine output with deepening jaundice and vomiting must be watched for, especially between the eighth and fifteenth days, as indicating liver failure from hepatic necrosis.

ACUTE AND SUBACUTE HEPATIC NECROSIS

Ætiology.—Hepatic necrosis, previously often called Toxic Jaundice, may be caused by a large variety of toxins, but coincident infection either by natural infective hepatitis or by transmitted serum or "syringe" jaundice is often impossible to exclude. The vulnerability of the liver to toxins is dependent partly upon dietary factors. Experimental work having shown that both carbohydrates and proteins—particularly the sulphur-containing amino acids—increase the resistance of the liver to poisons such as chloroform and phosphorus. Too high an intake of fat on the contrary is harmful, by causing fatty deposition in the liver (see Cirrhosis) and by increasing the effect of many toxic substances which are more soluble in fat than in water.

(a) *Intrinsic toxins*—An unknown toxin, which may develop in the later months of pregnancy—the toxic jaundice of pregnancy.

(b) *Extrinsic toxins*—i. Acute alcoholic poisoning.

ii. Delayed chloroform poisoning.

iii. Delayed poisoning with bromethol (Avertin) and other basal anæsthetics.

iv. Carbon tetrachloride used in treatment of ancylostomiasis.

v. Trinitrotoluene, tetrachlorethane, and other chemical solvents used in industry.

vi. Arsenic. (i) acute in arsenuretted hydrogen poisoning, (ii) subacute in poisoning with arsenphenamine preparations used in the treatment of syphilis, though in many cases a "syringe transmitted" virus infection is the cause.

vii. Phosphorus poisoning.

- viii. Gold poisoning, a rare result of chrysotherapy for skin diseases and arthritis. It occurred in 8 per cent. of 1500 patients who were given gold for arthritis.
- ix. Cinchophen (Agotan, Quinophan, Atophan); acetanilide.
- x. Mushroom poisoning (p. 345).
- xi. Infective hepatitis. In epidemics of infective hepatitis a small number of cases, usually less than 1 per cent., terminates in acute or subacute necrosis of the liver. Death does not often occur before the end of the third week. It is probable that some of the sporadic cases of acute hepatic necrosis which are otherwise unexplained are instances of fulminating infective hepatitis, but this cannot be regarded as established in the absence of tests for the presence of the virus.

Pathology.—Acute and subacute hepatic necrosis are caused by severe poisoning of the liver cells, the intracellular ferments of which are set free and produce autolysis. The necrosis may affect particularly the periphery of the lobules, or the centre, or it may be very diffuse. If extensive, death may ensue within a few days (acute necrosis). The old name of *acute yellow atrophy of the liver* is unsuitable, as the pathological change is necrosis and not atrophy. If a certain amount of liver tissue withstands the toxic onslaught, the patient may survive for some weeks or months, and at necropsy the destroyed liver is found to have become replaced by cellular fibroblastic tissue, the surviving islets of parenchyma being in a state of active proliferation. This is the stage of subacute necrosis. Finally some cases survive for many months or years, as the regenerated liver tissue compensates more or less adequately for what has been destroyed. When death occurs in such cases from the progress of the lesion or from some intercurrent disease, the liver presents the appearance known as multiple nodular hyperplasia, with numerous rounded nodules of regenerated functioning liver tissue separated by broad tracts of post-necrotic fibrosis. The stomach, duodenum and bile channels up to the smallest canaliculi are completely normal.

1. ACUTE HEPATIC NECROSIS

Synonyms.—Acute Yellow Atrophy of the Liver; Icterus Gravis.

Acute hepatic necrosis is a very rare and very fatal disease apart from the cases in which necrosis is the result of an extrinsic poison. It may occur at any age, but chiefly between 20 and 30. In adults, females are affected twice as often as males owing to the fact that pregnancy is one of the chief exciting causes, but the proportion is reversed in childhood.

Symptoms.—In the first stage jaundice is present with fever, malaise, vomiting, constipation and muscular pains. In about a third of the cases the patient suffers from general malaise for some time before the jaundice appears, and in rare instances jaundice is absent throughout. This first stage generally lasts for 5 or 6 days.

The second stage, that of hepatic failure, begins suddenly with drowsiness, headache, photophobia, restlessness and delirium with characteristic maniacal shrieking and wailing. Muscular twitching and occasionally general convulsions follow, and the patient may become violent. Transient squint is sometimes present, the pupils are generally dilated, and there is often an extensor plantar reflex. Retraction of the head may be present, and a lumbar puncture may be required to diagnose the condition from meningitis. Severe vomiting occurs, and the vomited material may contain altered blood. The tongue is dry and tremulous. The pulse becomes rapid and feeble, but the temperature is generally subnormal, though it often rises just before death. An erythematous rash is sometimes present and a moderate degree of œdema is usual. Purpura is common, and hæmorrhage may also occur from the gums, nose, kidneys, uterus and alimentary canal, and in the retinae. The sulphurous smell of mercaptan may be noticed in the breath. Coma finally develops with Cheyne-Stokes respiration and incontinence of urine and feces, the whole of the second stage lasting less than a week and often only 3 or 4 days.

The liver is often enlarged and tender in the first stage, but at the onset of severe

symptoms it rapidly diminishes in size, until the hepatic dullness disappears owing to the necrotic and flabby liver falling back and allowing the intestines to pass between it and the abdominal wall. The spleen is sometimes enlarged. Ascites is rarely detected during life, though it may be found after death. There is no anaemia, but there is moderate leucocytosis.

The urine contains bile and albumin, and casts are often present. There is no glycosuria. The percentage of nitrogen excreted as ammonia increases from the normal of about 5 to 20 owing to the acidosis, which causes ammonia to be fixed by organic acids before there is time for it to be converted into urea. Rounded discs of leucin and needle shaped crystals of tyrosin derived from autolysis of the liver cells may be deposited in the urine when it cools, but they are sometimes found only after concentration and may be absent altogether, though they are subsequently discovered in the liver. They are also occasionally found in the urine in typhoid fever, erysipelas, small pox and leukaemia, so that their presence is not pathognomonic of acute necrosis of the liver.

Diagnosis—The diagnosis cannot be made with certainty without biopsy or necropsy, but depends upon the occurrence of severe general symptoms with intense jaundice and evidences of bleeding. The serum bilirubin is high—20 mg per 100 ml or higher—and the serum albumin is greatly reduced.

Prognosis and Treatment—Acute hepatic necrosis is fatal in between 50 and 100 per cent. of cases, in spite of all treatment. Glucose must be given freely either by mouth or intravenously, or in both ways, from 10 to 15 oz a day orally and 2 to 3 litres of 5 to 10 per cent solution intravenously, 10 ml of 10 per cent calcium gluconate injected slowly intravenously is advised by some authorities, and a high fluid intake is essential. Insulin is not of value and may be harmful. The use of methionine, cysteine and choline, though justifiable experimentally have so far been of little demonstrable value in man.

2 SUBACUTE HEPATIC NECROSIS AND NODULAR HYPERPLASIA

If jaundice persists for more than 3 months after an attack of hepatitis it is probable that permanent damage has been done to the liver, and the longer the jaundice lasts, the more likely is this to be true. Other patients may make an apparent recovery from an attack of hepatitis but the jaundice returns and the illness pursues a relapsing course. In still other cases there is no clear history of an acute attack and the patient presents himself—or more commonly herself—with a chronic jaundice of insidious onset. In all such cases the structure of the liver has been so gravely disorganised that the normal connections of the portal venules and the biliary canaliculi cannot be re-established and the patient eventually succumbs from portal hypertension or choleraemia. The clinical picture is that of cirrhosis (pp 674, 678), except that jaundice is more prominent. The differentiation of subacute hepatitis from obstructive jaundice may be difficult at the bedside but great help is usually obtained from biochemical tests. Diagnostic laparotomy should be avoided if possible in subacute hepatitis as operation is not well borne. The hepatic functions are much more gravely impaired than in obstructive jaundice and the hypoproteinaemia and reversal of the ratio of albumin and globulin in the plasma are of considerable diagnostic value. The prognosis is unfavourable and death may occur after a duration of a few months or years but in some cases nodular regeneration is sufficient to maintain liver function for a normal length of life. Treatment should follow the same lines as for acute hepatic necrosis in the early phase of the illness and as for cirrhosis in the later.

FAITY INFILTRATION OF THE LIVER

Synonyms—Hepatosi, 'Liverishness'

Individuals who habitually overeat and consume large quantities of alcohol and

carbohydrate, but take only small amounts of protein in their diet, are likely to develop fatty infiltration of the liver. The condition is frequent in the tropics where it is called "tropical liver" and is due to the above factors, combined sometimes with the effects of malaria, amœbiasis or enteric fever. Excessive consumption of alcohol does not seem by itself to cause the condition, provided the dietary protein intake is sufficient. The condition can be demonstrated by liver biopsy and is rapidly recoverable under conditions of rest and high protein feeding.

It is to be distinguished from a much more serious form of liver disease found in children in tropical countries, called serous hepatosis, which is also due to protein deficiency, in this condition there is œdema of the liver with exudation of an eosinophilic coagulum, fibrosis and later true cirrhosis.

Symptoms—No close correlation between the degree of fatty infiltration and the clinical symptoms can be drawn, but enlargement of the liver is the most important and characteristic sign. It is usually tender and firm. Ascites is rare, but slight anæmia is frequent, which in a few cases may be macrocytic. Albuminuria occurs in fully half the cases. The patient complains of a feeling of discomfort, rarely amounting to pain in the right hypochondrium, and symptoms of alcoholic gastritis especially morning anorexia and nausea are often present. The complexion is often sallow and there is sometimes a slight degree of jaundice. He says he is "liverish" or "bilious", he is irritable and depressed, and complains of a feeling of general unfitness, headache and drowsiness. Gastric and intestinal flatulence may occur as a result of deficient absorption of gas secondary to slight portal obstruction.

Periods of comparative well-being may alternate with acute exacerbations or—"liver attacks" which are generally caused by increased alcoholic excess, by over-eating and sometimes by exposure to cold. During such an attack the liver becomes larger and more tender, and the stretching of the capsule may cause acute pain. With suitable treatment an attack usually subsides within a fortnight and even in severe cases a month or 6 weeks is generally sufficient to restore the patient to good health. If he becomes tetotal complete recovery usually occurs, otherwise cirrhosis eventually develops in many cases.

Treatment—The patient should be kept in bed on a high protein diet until all symptoms have disappeared and the liver is no longer tender. He should avoid alcohol permanently and reduce his weight if this is excessive by restricting both carbohydrates and fat. Additional vitamins and amino acid preparations are of little proved value. It should be pointed out to the patient that his liver has become abnormally vulnerable, and that even small quantities of alcohol are dangerous to him and may eventually cause cirrhosis and death.

CIRRHOSIS OF THE LIVER

Synonym.—Chronic Interstitial Hepatitis

Cirrhosis of the liver is a condition in which the liver hardens as a result of the development of new fibrous tissue. The pathological picture varies considerably, but the primary feature is always a loss of hepatic glandular cells associated with an increase in fibrous tissue. New liver cells regenerate, and at this stage the liver is often uniformly enlarged, later scar-tissue is formed which by contraction distorts the liver, diminishes its size and twists the blood vessels and bile ducts to an extreme degree. Fibrosis may be fairly uniform throughout the whole organ, or very irregularly disposed, according to the ætiological factors discussed below. Pathologists describe five main types, based on the histological picture, namely, the common portal or multilobular cirrhosis (p 674), cirrhosis associated with nodular hyperplasia (p 672), pericellular cirrhosis (in congenital syphilis, p 681) biliary or peribiliary cirrhosis (p 679) and the very specialised form known as haemochromatosis (pigmentary cirrhosis, bronzed diabetes, p 680).

Ætiology—Two main causes are postulated which between them may explain the majority or even all forms of hepatic cirrhosis—direct damage to the liver cells produced by viruses, microbic infections or toxic substances, and dietary deficiencies acting indirectly by interfering with the nutrition of the liver cells which gradually degenerate and die.

The first factor has long been accepted as important, but the recent work on infective hepatitis, particularly by the technique of liver puncture, has proved that not all acutely damaged livers recover but some progress slowly to the stage of typical cirrhosis. Toxic chemical substances may also produce the same effect.

Dietary factors in cirrhosis have been extensively studied experimentally, and it was found that in animals high fat diets induced fatty degeneration of the liver with subsequent cirrhosis, the inference was drawn that the excess of fat interfered in some way with the nutrition of the liver cells, which died and were replaced by fibrous tissue. It was also discovered that administration in adequate dose of two natural substances of the body, lecithin and choline, reduced the fat content of the liver and prevented cirrhosis. Casein a natural protein, was equally effective, and its activity was proved to be due to the presence of the amino-acid methionine, an essential substance for the production of lecithin. Lecithin, in fact, appears to be an essential medium for the transport of fat in the body, and if lecithin or the methionine necessary for its manufacture are deficient, fat accumulates in the liver cells and degeneration follows.

Further experiments showed that rats fed on diets deficient in first class protein also developed cirrhosis, and it was found that the critical deficiency in the low protein diet which brought about necrosis was of the two sulphur-containing amino-acids, methionine and cysteine, the first being the more important.

It is probable that toxic and dietetic factors often act together in man and that the development of cirrhosis after acute hepatitis is far more likely to occur in individuals whose diets have been previously deficient in proteins than in others. Certainly the two main groups of post infective and nutritional cases are not always easy to distinguish either clinically or histologically.

PORTAL OR MULTILOBULAR CIRRHOSIS OF THE LIVER

Synonyms—Portal or Multilobular Cirrhosis, Laennec's Cirrhosis

Definition.—The portal or multilobular form of cirrhosis of the liver is so much the most common that it is generally described shortly as cirrhosis of the liver. It is a disease in which degeneration of the hepatic cells occurs in association with fibrosis spreading from the portal spaces to enclose various numbers of lobules.

Ætiology—The general problems of ætiology have already been discussed. The disease is generally fatal about the age of 50 but a distinct group of cases occurs in childhood. It is three times more common in men than in women, but only slightly more so in boys than in girls. Cirrhosis is in rare instances familial, presumably as a result of an inborn defect of the liver cells which renders them abnormally vulnerable to toxins and liable to premature degeneration, this may then be associated with chronic lenticular degeneration. It is more common in individuals who follow a sedentary occupation than in those who lead an active life, and among the poor than the well to-do.

The majority of patients with cirrhosis of the liver in Britain have indulged excessively in alcohol, it is three times more common among people connected with the liquor trade than among the general public. Cases occur, however, especially in India, Egypt and Dutch East Indies, and in children in which alcoholic excess can be excluded with certainty. Thus cirrhosis is not infrequent among Brahmans, the majority of whom indulge in large quantities of ginger, cardamom, red pepper and other spices, but never touch alcohol.

Pathology.—Cirrhosis never develops experimentally in animals as a result of chronic alcoholic poisoning, although fatty changes and occasionally necrosis with a slight degree of small-celled infiltration may be produced. It occurs in less than 3 per cent. of drunkards dying from the effects of alcoholism, though it is at least three times as frequent amongst inebriates as amongst the non-drinking public; its geographical distribution does not correspond with that of chronic alcoholism, and when excessive indulgence in alcohol leads to nervous changes, cirrhosis of the liver is rare.

It is probable that the main factor concerned is the low-protein diet which alcoholics often take, combined with their high calorie intake in the form of alcohol. There may also be deficiency of other essential food factors owing to the substitution of alcohol for ordinary food with consequent serious imbalance of the diet as a whole. Associated virus hepatitis, other infections such as malaria or amœbiasis and possibly some constitutional vulnerability of the liver may be additional factors concerned.

The size of the liver varies greatly; it may be much smaller or much larger than normal, depending upon the relative degrees of hyperplasia and fibrosis.

Its surface is irregular. The projections may be as small as those of a granular kidney, but more frequently they give rise to a hob-nailed appearance.

The obstruction to the intrahepatic branches of the portal vein produces a rise in pressure in its tributaries; this results in dilatation of the collateral circulation which normally exists between the portal and general venous systems. This compensatory circulation is carried out by the following groups of vessels.

1. An anastomosis may develop within the liver between the branches of the portal vein and the intralobular veins. Large branches pass from the liver and its capsule to the phrenic and intercostal veins, where the liver and diaphragm are uncovered by peritoneum. Occasionally a single large vein passes from the liver in the falciform ligament by the side of the obliterated umbilical vein to join the veins of the abdominal wall at the umbilicus; the subcutaneous veins around and above the umbilicus are consequently dilated, and a large bunch of dilated veins may form at the umbilicus (*caput medusæ*). In rare cases a loud venous hum may be heard with the stethoscope at this point or below the xiphisternum.

2. The gastric veins anastomose with the œsophageal veins, which open into the azygos veins; the veins in the œsophagus, especially its lower end, may become greatly dilated.

3. The inferior mesenteric vein communicates through the superior and middle hæmorrhoidal veins with the inferior hæmorrhoidal vein, which is a branch of the internal iliac vein. This might be expected to give rise to hæmorrhoids, but they are hardly more common among patients with cirrhosis than in individuals with healthy livers.

4. Additional veins unite the radicles of the portal veins in the intestines and peritoneum with the inferior vena cava and its branches. These include the retro-peritoneal veins, which are often greatly enlarged, especially in the neighbourhood of the kidneys.

Symptoms.—About 50 per cent. of patients with cirrhosis of the liver die from some intercurrent disease or accident. Such cases are generally described as latent. But in the majority symptoms due to the condition were probably present before death, and the fatal result of the intercurrent disease or accident was often due to the diminished power of resistance which results from cirrhosis. In some cases, however, the disease may be genuinely latent, owing to compensatory hyperplasia of the liver cells and to the development of an efficient collateral circulation between branches of the portal vein and systemic veins.

In a large majority of cases the symptoms caused by cirrhosis are preceded by those of fatty infiltration, which have already been described (p. 673), and alcoholic œsophagitis and gastritis have generally been present for many years. The patient

habitually wakes in the morning with a feeling of nausea and no desire for breakfast, violent retching often occurs, and he then vomits a small quantity of alkaline watery fluid, after which some bile stained mucus may appear. A sense of uncomfortable fullness is also felt in the epigastrium after other meals, and the nausea and vomiting may recur. The appetite is poor, and there is a special repugnance for meat. When cirrhosis develops, the symptoms due to catarrh are exaggerated by the congestion of the gastric and intestinal mucous membrane caused by portal obstruction, this leads to the secretion of still more mucus, and by preventing absorption of gas leads to flatulence, which aggravates the feeling of distension already present. Flatulence is a constant early symptom and may be the earliest sign of portal congestion, it is 'le vent avant la pluie'.

The complexion is generally sallow and bloated with dilated capillary or arterial angiomata, especially over the nose and cheeks. In the later stages the face is drawn the cheeks and eyes are sunken, and the conjunctivae are congested and often slightly tinged with bile. The skin of the body is dry and inelastic, numerous spider angioma appear on the face, neck and back as the disease progresses and red or purple areas of skin may be produced by the uniform distension of small venules. Purpura and various forms of erythema may occur.

The tongue is flabby and furred, the gums readily bleed and pharyngitis is common owing to chronic irritation by alcohol. The breath is often offensive as a result of oral sepsis.

The patient is generally constipated, but attacks of diarrhoea often occur, especially during the last few weeks of life.

In a large proportion of cases the liver is enlarged when the patient is first seen. Its lower border can generally be felt below the costal margin in the right nipple line, but ascites and occasionally flatulent distension of the intestines or obesity may render it impalpable. It is always hard, and its edge can consequently often be felt even when it is not enlarged. An enlarged liver can be observed to shrink as the disease progresses until it ceases to be palpable, and after death it may be found to be considerably smaller than normal. The irregular surface of the liver may be recognised by palpation, and in contrast with its tenderness in the pre cirrhotic stage is insensitive.

Discomfort is often felt in the right hypochondrium, but pain occurs only if the disease is complicated by an attack of perihepatitis.

In about 35 per cent of cases jaundice occurs. It is generally slight and is often transient. In the absence of jaundice, excess of bile pigment may be found in the blood.

In 80 per cent of cases the spleen is enlarged. Owing to its hardness it is easily felt unless it is obscured by ascites or intestinal flatulence. Discomfort or pain may result from stretching of the capsule if rapid enlargement occurs, more frequently it is due to perisplenitis. When both the liver and spleen are much enlarged the left lobe of the former may overlap the latter.

Hæmatemesis occurs in about 25 per cent of cases. It may be an early symptom and is often the first indication of the presence of serious disease, though it is generally preceded by symptoms of gastritis. It is less common after ascites has developed. The hæmatemesis generally takes the form of a single large hæmorrhage but sometimes a smaller quantity is vomited during several days. It is generally repeated only after a considerable interval. The blood collects slowly in the stomach and often passes into the intestine, causing melæna without hæmatemesis. When a considerable quantity has collected in the stomach, the distension causes it to be vomited, small quantities are not brought up unless vomiting occurs from some independent cause. Death directly from hæmatemesis is unusual in cirrhosis and accounts for less than 5 per cent of the mortality. In the majority of cases the hæmorrhage is a result of rupture of varicose veins of the œsophagus, especially in the lower 3 in.

where they can often be demonstrated with the radiograph. The blood runs into the stomach, though in severe cases it may well up directly from the œsophagus. Hæmorrhage may also occur from minute erosions secondary to acute gastritis, sometimes associated with varicose veins. The erosions are very difficult to discover post mortem and possibly in some cases there is no actual loss of surface, the hæmorrhage corresponding with the bleeding which occurs from other mucous membranes. In very rare cases melæna may result from thrombosis of the portal vein or one of its branches (see p. 688).

Epistaxis is common. The hæmorrhage generally comes from a point on the anterior part of the septum. In the late stages oozing from the nose may occur, as well as from the gums, lungs, kidneys and uterus, as a result of the toxæmia caused by hepatic insufficiency and deficiency in vitamin K, and small hæmorrhages often occur under the skin. Hæmoptysis, however, is generally due to the cirrhosis being associated with pulmonary tuberculosis.

Ascites is present in most cases of cirrhosis which run their full course. It is a late symptom in uncomplicated cases, and is often absent if the patient dies from some independent cause or from hæmatemesis at a comparatively early stage. The onset is generally gradual, but it occasionally develops suddenly after a blow on the abdomen, a chill or an acute infection, it is also acute in portal thrombosis. It sometimes disappears spontaneously. It is partly due to portal congestion, as the intra-hepatic branches of the portal vein are compressed, some being completely obliterated, occasionally others are thrombosed, and in rare cases thrombosis of the portal vein itself occurs, but this is not the sole cause as the fluid may collect with extreme rapidity instead of *pari passu* with the changes in the liver, and it is often absent when the portal pressure is high as shown by the occurrence of hæmatemesis. In some cases it is secondary to chronic peritonitis. The ascitic fluid is clear and sometimes slightly bile stained. Its reaction is alkaline, its specific gravity between 1.008 and 1.015, and a large proportion of the cells it contains are endothelial. When the ascites is due to chronic peritonitis the specific gravity is greater than 1.015, more albumin is present, flakes of fibrin may form on standing and polymorphonuclear cells are found. When 50 per cent. or more of the cells are lymphocytes, tuberculous peritonitis is probably present. In rare cases the ascites is chylous or chyliform, still more rarely it is hæmorrhagic.

Oedema of the ankles is frequent, but it is rarely severe, though occasionally it spreads up the legs to the abdomen and back. It often develops before or at the same time as the ascites, in which case it may be the result of hypoproteinaemia, but most frequently it follows it and is then often due to thrombosis of the inferior vena cava. Pressure from the ascitic fluid may play some part, since removal of this may lessen the oedema.

Muscular weakness and loss of energy may be the earliest symptoms, they are constant in the late stages. The muscles are flabby and atrophied, and marked wasting of the whole body occurs.

The rise in intra-abdominal tension caused by flatulent dyspepsia and later by ascites is frequently followed by the development of hernias.

The urine is diminished in quantity and the specific gravity is high. It is very acid and high coloured and a large deposit of urates generally forms on standing. It contains excess of urobilin, but even when slight jaundice is present bile pigment is often absent. In the late stages the percentage of nitrogen excreted as ammonia increases at the expense of urea, this is due to ammonia being required to unite with the excess of organic acids present, and not to inability of the liver to form urea, as ammonia given by the mouth is still excreted as urea. In the last days of life leucine and tyrosine crystals are sometimes found.

Albuminuria is occasionally present as a result of hepatic toxæmia, nephritis or congestion of the kidneys from heart failure. Glycosuria is rare as the glycolytic

function of the liver is maintained to a certain extent even in advanced cases. The blood may be normal, but in a number of cases anæmia develops, due either to deficiency of iron, proteins, or to hæmorrhage from œsophageal or other enlarged veins. In some cases the anæmia is hyperchromic or macrocytic, but more usually it is hypochromic and normocytic.

The temperature is often raised in rapidly progressing cases apart from complications such as tuberculosis and urinary infection.

In the late stages of cirrhosis the toxæmia which results from hepatic insufficiency gives rise to restlessness, irritability, muttering delirium and finally to coma. Severe colitis with large amounts of blood and mucus in the stools is a frequent complication.

Nervous symptoms may also be present as a direct result of chronic alcoholism. Delirium tremens may follow a drinking bout and occasionally a hæmatemesis. Slight mental disturbance and muscular tremor are common, but neuritis is rare.

Active tuberculous disease is found more frequently in patients dying with cirrhosis of the liver than with other diseases. This is probably due to the diminished resistance to tuberculous infection caused by chronic alcoholism. The lungs are most often affected, phthisis being the cause of death in 15 per cent. of cases of cirrhosis, and tuberculous pleurisy is not uncommon. Either the cirrhosis or the phthisis may be completely latent and remain undiscovered until death. Tuberculous peritonitis is found in 10 per cent. of cases; the accompanying ascites is often thought during life to be due to the cirrhosis. The lungs are generally also involved. The majority of cases of tuberculous peritonitis in adult males are associated with cirrhosis.

Diagnosis.—An enlarged, hard liver in an alcoholic individual is generally the result of cirrhosis. The occurrence of hæmatemesis, enlargement of the spleen or slight jaundice makes the diagnosis still more probable. The enlarged hard liver, which is produced by chronic venous congestion in heart failure, may be difficult to distinguish from cirrhosis if the patient is seen when the heart is no longer failing. A history of heart failure with pain in the hepatic region and any evidence of existing heart disease point to congestion.

The diagnosis from syphilis and from malignant disease of the liver is discussed elsewhere (p. 687).

The symptoms in the last stages are often indistinguishable from those of uræmia, and the diagnosis may be very difficult in the absence of a full history. But a much increased blood urea with high blood pressure, albuminuric retinitis or the presence of a large quantity of albumin with casts in the urine would prove that uræmia is present.

Prognosis.—If an individual with alcoholic cirrhosis becomes completely teetotal in the pre-ascitic stage, there is a good chance that the disease will not progress and that his symptoms will disappear. Even the damage done to the liver can be repaired to some extent by hyperplasia of its cells, a large liver being therefore a favourable sign, and the danger of hæmatemesis, together with the other ill effects of portal congestion, may be overcome by a sufficient development of the anastomoses between the portal and general venous systems.

Much, therefore, depends upon the patient's character, as, if he is unable to control his desire for alcohol, the disease is certain to advance to a fatal issue. The younger the patient the more chance there is for functional compensation to occur, but the prognosis is always bad in children. However completely latent the disease may become, much of the damage to the liver is, of course, permanent, and the patient's power of resisting acute infections and other diseases is materially reduced.

Fever is a serious symptom, as it indicates rapid advance of the disease or the presence of some complication. The development of jaundice, and particularly of ascites, are of serious significance.

In rare cases the disease runs a subacute course, death occurring within a few months of the onset of symptoms. Such cases are most frequent in comparatively

young adults who are heavy drinkers. The liver is painful and tender, fever is present, emaciation is rapid, and multiple hæmorrhages are likely to occur.

Treatment.—As has been indicated, the real treatment of cirrhosis must be prophylactic, but considerable alleviation and prolongation of life can often be achieved by treatment even when the disease is fully established. Alcohol must be absolutely prohibited for the rest of the patient's life, and no medicine containing alcohol should be prescribed.

The diet in the early stages should be that required for the treatment of the associated chronic gastritis, and curries, pickles, ginger, all highly seasoned food, vinegar, mustard, pepper, high game must be restricted. In the late stage, when symptoms of hepatic insufficiency are present, the diet should consist of milk, milk foods, vegetable purées and fruit; a quarter of a pound of dextrose in a pint of lemonade or other fruit drink should be given daily. High protein feeding is certainly important as a preventive and should be carried on throughout treatment, milk concentrates being useful when meat proteins are badly tolerated. When ascites is present rigid sodium restriction and a low fluid intake, combined with the use of mercurial diuretics may be most effective and completely relieve the fluid distension. A course of whole liver injections given intramuscularly daily for 2 to 3 weeks provides vitamins and lipotropic factors and may also lead to improvement. The bowels should be kept regular by means of Epsom salts. No other drugs are required in uncomplicated cases. The treatment of the gastritis, ascites and hæmatemesis is considered in detail elsewhere.

Surgical Treatment.—Many types of operation have been devised to try and relieve portal hypertension in cirrhosis of the liver. Most of these operations have aimed at shunting the portal blood into the systemic circulation either by a porto-caval or a lieno-renal anastomosis. Ligation of the hepatic artery has also been carried out on the assumption that the pressure in the hepatic artery is directly communicated to the portal system through sinusoidal connections between the two systems.

These operations have a high operative mortality and in many cases have proved no more successful than medical treatment. In general they may be expected to help patients who have bled from œsophageal varices rather than those suffering from ascites.

BILIARY CIRRHOSIS

There has been much discussion whether it is justifiable or desirable to separate this form of cirrhosis from others, but it makes for clearness to do so. Two forms are described.

PRIMARY HYPERTROPHIC BILIARY CIRRHOSIS

Definition.—A chronic disease of the liver occurring in childhood and early adult life, accompanied by persistent jaundice, with great enlargement of the liver due to fibrosis surrounding the smaller bile-ducts and striking splenomegaly.

Ætiology.—Quite unknown, but thought to be primarily an inflammation of the small bile-ducts. This was Hanot's view, and the disease was formerly often described under his name. It is seen most commonly between the age of 20 and 30 years, but also occurs in children. An hereditary and familial incidence have been noted.

Pathology.—The liver is very large, smooth and coloured deep green from the chronic jaundice. Microscopically dense fibrosis surrounds the small bile-ducts and spreads out to surround the lobules, often single lobules, but the liver cells remain unaltered. In the later stages the lobules are invaded by the fibrosis, and the pathological picture is then almost identical with ordinary portal cirrhosis. It is chiefly for this reason that many writers refuse to separate this form of cirrhosis. The spleen,

however is generally much larger than in portal cirrhosis, and may occasionally even exceed the liver in weight

Symptoms—The onset is slow and jaundice which waxes and wanes but persists until death is the most obvious clinical feature. Abundant bile pigment is present in the urine throughout. Reasonable health may be maintained for years interrupted by occasional crises of abdominal pain and fever. The abdomen is often greatly distended by the very large liver and spleen and there is much flatulence. In the later stages hæmorrhages are not infrequent and the patients become very thin and poorly nourished.

Prognosis is bad. The average duration is about 5 years and unless intercurrent disease supervenes the termination is from gradual hepatic failure ending in coma.

Treatment—As for portal cirrhosis.

SECONDARY OBSTRUCTIVE BILIARY CIRRHOSIS

Definition—A chronic fibrosis of the liver spreading from the larger bile ducts which have been obstructed and often infected (cholangitis) by previous disease.

Ætiology—Obstruction of the larger bile ducts with cholangitis and often pericholangitis due to gall stones, carcinoma or other obstructive disease. This condition is seen more often by surgeons than physicians.

Pathology—The liver is at first enlarged but never so large as in the hypertrophic variety of biliary cirrhosis. Jaundice is constant and in section the liver is dark green with obvious dilated large bile ducts filled with inspissated bile. The fibrosis spreads out quite irregularly from the ducts as in portal cirrhosis and the liver cells are damaged and necrosed. There is considerable new bile duct proliferation. The spleen is sometimes normal, sometimes enlarged but never of the size found in the hypertrophic variety.

Symptoms—are those of the primary disease obstructing the bile ducts followed only later by those of cirrhosis.

Prognosis—depends on recognition of the primary cause and whether it can be relieved before cirrhosis has occurred.

Treatment—is essentially surgical and preventive. Once cirrhosis is fully established the treatment is the same as in portal cirrhosis.

HÆMOCHROMATOSIS

Synonyms—Pigmentary Cirrhosis. Bronzed Diabetes.

Ætiology and Pathology—Hæmochromatosis is a rare disease in which large quantities of hæmosiderin, an iron containing pigment are deposited in various parts of the body especially the liver, upper abdominal lymph glands, pancreas, suprarenal glands and skin but very little in the kidneys and spleen. The deposition of pigment is associated with ordinary multilobular cirrhosis of the liver and cirrhosis of the pancreas and the latter by involving the islands of Langerhans may give rise to diabetes mellitus. It occurs in about 7 per cent of cases of cirrhosis of the liver in males and hardly ever in females. There is no excessive hæmolysis. The quantity of iron deposited is much greater than in hæmolytic anæmias in which the excess of iron is chiefly in the liver and kidneys whereas in hæmochromatosis it is chiefly in the liver, pancreas and abdominal glands to which it passes from the liver and pancreas. The condition appears to be due to some abnormal and excessive absorption of iron from the alimentary tract and since the body is unable to excrete this iron to any extent it is stored in the liver where it causes degeneration of the liver cells. In advanced cases 40 g of iron may be deposited in the body compared with the normal 2 to 4 g. Multiple blood transfusions may similarly lead to excessive iron deposition as may some forms of hæmolysis but true cirrhosis is only very rarely

produced in this way. The disease is extremely chronic. Primary carcinoma of the liver occurs in hæmochromatosis somewhat more frequently than in simple cirrhosis of the liver.

Symptoms.—The symptoms are those of cirrhosis and diabetes associated with pigmentation. The liver and spleen become progressively larger. Ascites may occur and the subcutaneous veins are sometimes enlarged. The skin is generally pigmented a slaty colour, especially in the exposed parts of the body, and has a wrinkled parchment-like appearance. The lesion of the suprarenal cortex may give rise to symptoms of Addison's disease, the pigmentation of the skin being sometimes due to melanin and not to hæmosiderin, and pigmentation of the buccal mucous membrane may occur. In the rare cases in which no pigmentation is present a diagnosis can be made only after death. In most cases symptoms of severe diabetes with acidosis appear suddenly, but they may be absent to the end. Genital hypoplasia and loss of secondary sex characteristics are commonly found.

Diagnosis.—The disease can be diagnosed with certainty only when pigmentation, diabetes and cirrhosis are associated together. When two of these conditions are present alone, a definite diagnosis is impossible. It can, however, be made with a considerable degree of probability if well marked bronzing is associated with cirrhosis, even in the absence of diabetes. The serum iron level is raised, normal = 80 to 180 μg per 100 ml, and it can be shown that the iron binding capacity of the serum proteins is completely or almost completely saturated. In doubtful cases biopsy of a pigmented area of skin settles the diagnosis.

Prognosis.—So long as no diabetes is present the prognosis is not worse than that of uncomplicated cirrhosis, but the onset of diabetes is always serious. With insulin, however, a normal life can generally be led for several years, death being finally caused by the cirrhosis. Heart failure, due to involvement of the myocardium, is the cause of death in a number of patients.

Treatment.—The treatment is that of cirrhosis and diabetes. The latter requires large doses of insulin, with the aid of which the diet can be balanced without special difficulty. Repeated venesections to remove iron from the body have been tried with success and it is possible that the monthly loss of iron occurring with menstruation is the reason why the disease so rarely affects women.

CONGENITAL SYPHILIS OF THE LIVER (PERICELLULAR CIRRHOSIS)

Ætiology and Pathology.—The liver is affected in 50 per cent of infants with congenital syphilis. This great frequency is probably due to the *Treponema pallidum* passing through the placenta and the umbilical vein direct to the fetal liver, which is the first organ it reaches, and which is consequently found to contain it in larger numbers than any other organ.

Congenital syphilis produces diffuse changes in the liver very different from the focal lesions of acquired syphilis, except in rare cases occurring in later childhood, in which caseous gummata are found. The liver is smooth and uniformly enlarged and is firmer and paler than normal. The changes are due to pericellular cirrhosis, the result of diffuse infiltration with embryonic connective-tissue cells between the individual liver cells. These may be associated with small collections of round cells, or milary gummata, which resemble tubercles when seen by the naked eye.

The spleen is generally enlarged and hard. Diffuse small celled infiltration or fibrosis may be found in the kidneys, pancreas, testes, suprarenal glands and lungs.

Symptoms.—Symptoms pointing to disease of the liver are not often present in infants with congenital syphilis, but on examination the liver and spleen are found to be enlarged and abnormally firm. The liver normally extends farther down in young children than in adults owing to its relatively larger size and the more horizontal position of the ribs. Only definite enlargement and abnormal hardness of the

liver can, therefore, be regarded as important in the absence of other evidence of congenital syphilis. Jaundice is rare; it may be present from birth or, less frequently, it develops a few weeks later.

Diagnosis.—The diagnosis is generally easy owing to the well-marked signs of congenital syphilis present in other parts of the body together with a positive Wassermann reaction. In the absence of such signs the diagnosis must be made from rickets, tuberculosis and gastro-intestinal infection, and, when jaundice is present, from the other more common causes of *icterus neonatorum* (p. 746).

Prognosis.—The prognosis depends upon the general condition of the infant. It is less favourable in delayed congenital syphilis than in acquired syphilis owing to the changes being generally more widespread.

Treatment.—The treatment is that of congenital syphilis.

ACQUIRED SYPHILIS OF THE LIVER

1. *Secondary syphilis.*—Jaundice formerly occurred in about $\frac{1}{4}$ per cent. of cases of syphilis at the same time as the roscola and enlargement of glands, but it is now almost unknown. Rapid recovery generally followed treatment with mercury, but occasionally death occurred from acute hepatic necrosis. It must, of course, be distinguished from the jaundice following treatment with organic arsenical preparations (p. 229).

2. *Tertiary syphilis.*—**Ætiology.**—Gummata of the liver are becoming increasingly uncommon; but in more than half of the cases in which other active syphilitic lesions are found at necropsy the liver is affected.

Syphilis affects the liver three times as frequently in men as in women. The disease is generally discovered between 10 and 20 years after infection, but in rare instances it has occurred within a year.

Pathology.—In the early stages a mass of pink syphilitic granulation-tissue, sharply separated from the healthy liver, is found; necrosis soon occurs in the centre, which becomes yellowish-white. The caseous mass is later surrounded by a fibrous capsule; as this contracts, the liver becomes more and more deformed. The capsule of the liver in the neighbourhood of a gumma is thickened, and adhesions often develop between it and the adjacent organs, the diaphragm and anterior abdominal wall. Unless they are very large, gummata, which are generally multiple, are slowly absorbed till they may finally be represented by nothing more than scars, from which fibrous tissue radiates into the capsule. Much less often a large part of the liver is diffusely infiltrated. Gummata are often associated with some degree of diffuse syphilitic hepatitis, which produces cirrhotic changes in long-standing cases, especially if the patient is alcoholic or has been treated with arsenamine derivatives.

Symptoms.—Gummata and cicatrices are sometimes found after death without having led to any symptoms. The nature of the symptoms they produce depends upon the size, extent and position of the lesions. Before any localising symptoms appear the patient may complain of general ill health, which is often associated with gastro-intestinal symptoms. The first symptom pointing to disease of the liver is generally pain in the right hypochondrium, the result of perihepatitis over a gumma. The pain may radiate to the right shoulder and is sometimes associated with local tenderness.

Irregularities on the anterior surface of the liver produced by gummata and by the contraction of cicatrices are easily palpable. The diagnosis from malignant disease can be made by the presence of a positive Wassermann reaction and the rapid disappearance of a gumma with antisyphilitic treatment; jaundice and ascites are much more common in malignant disease, in which the constitutional symptoms are generally more severe, and there may be evidence of a primary growth in some

other situation. In hydatid disease the liver is smooth apart from the tumour itself, but in syphilis it is often irregular, owing to the contraction of cicatrices. The presence of eosinophilia points to hydatid disease. A gumma near the gall bladder or in the left lobe of the liver may simulate a growth of the gall-bladder or of the stomach respectively.

Irregular fever sometimes occurs, disappearing with antisyphilitic treatment. In rare cases an infected gumma may break down, when the symptoms and sequelæ do not differ from those of other forms of hepatic abscess.

Jaundice is infrequent in syphilis of the liver, but it is occasionally produced by the pressure of a gumma or of a syphilitic cicatrix, in very rare cases this is associated with attacks of pain indistinguishable from biliary colic due to gall-stones.

Ascites is uncommon, but may result from pressure of gummata or cicatrices on the intrahepatic branches of the portal vein or less frequently on the vein itself in the portal fissure, in which cases thrombosis is likely to occur.

When a gummatous liver is associated with amyloid disease, the clinical aspects of the latter may be so prominent that the presence of a gumma is overlooked. The liver and the spleen are enlarged, ascites and œdema are present, and the urine contains albumin and casts.

Diagnosis—The possibility of syphilis should always be remembered in obscure hepatic disorders. Apart from a history of infection and the presence of other syphilitic lesions, the Wasserman reaction should always be tested in doubtful cases. As, however, infection with syphilis does not prove that every lesion present is syphilitic, the final proof of the nature of the disease is obtained only if great improvement or complete recovery results from antisyphilitic treatment. The diagnosis from cirrhosis of the liver is suggested by the greater irregularity in the enlargement of the liver. Hæmatemesis, dilated veins on the abdominal wall, jaundice and symptoms of gastritis and hepatic insufficiency are much more common in cirrhosis, and the nutrition suffers at an earlier stage.

Prognosis—The prognosis of syphilitic lesions of the liver is good if treatment is actively carried out at an early stage. In the rare cases in which the symptoms are due to pressure exerted by cicatrices and not by gummata little or no improvement can occur.

Treatment—As soon as the possibility of syphilis is recognised a full course of penicillin should be given. Large doses of iodide should then be ordered and ill results rarely follow the administration of as much as gr. 40 of sodium iodide every 6 hours, a patient is more likely to suffer from iodism if the dose is gradually increased from a small quantity than if full doses are given at once. Mercury should also be given, but no organic arsenical preparation because of the danger of hepatic necrosis occurring as a result of its action on the already damaged liver cells.

AMÆBIC HEPATITIS AND HEPATIC ABSCESS

This is dealt with under Amœbiasis (see p. 279)

HYDATID DISEASE OF THE LIVER

Ætiology and Pathology—Hydatid disease is caused by swallowing the ova of the echinococcus or hydatid worm (p. 324). The infection often dates from childhood, even when the disease is not recognised till middle life. The ova are conveyed by the fingers from playing with a dog, the skin, paws or muzzle of which have been contaminated with infected faeces. Infection may also result from contaminated water, salads, watercress or uncooked vegetables. The disease occurs in many countries, and is common in Australia and New Zealand, where with a population of 1½ millions there are 150,000 dogs, of which about a third are spreading myriads of hydatid

eggs about the country homesteads every day. It also occurs in England, but is rare in North America.

When the eggs are swallowed, the embryos set free by digestion of the egg-shell pass through the walls of the stomach or small intestine into the radicles of the portal vein, by which they reach the liver, where they are generally arrested. The embryo now forms a small cyst, with an internal, nucleated, protoplasmic layer (the endocyst) and an external "cuticular membrane". The reaction in the surrounding tissues results in the formation of a fibrous capsule. After a time a dozen or more buds project from the endocyst, and develop into daughter cysts, identical in structure with the mother cyst; these soon separate from the endocyst of the mother cyst and become free.

The fluid in the cyst is clear or very slightly opalescent, with a specific gravity between 1.005 and 1.011. It contains chlorides, phosphates, traces of sulphates and succinates, and some unknown toxic substances, but only occasionally traces of albumin or sugar. Hooklets and less often hydatid heads may be found in the fluid.

The liver is involved in 60 per cent. of cases of hydatid disease in man. A single cyst is generally present, but there are occasionally multiple cysts, or single ones may develop in more than one organ.

Symptoms.—The patient remains in good health until the weight of the cyst, its pressure on surrounding parts, or the occurrence of a complication, such as rupture or suppuration, causes symptoms. A hydatid cyst of the liver may remain latent and be discovered only after death or in the course of a routine examination of the abdomen in a patient without abdominal symptoms.

The increasing size of the liver may give rise to a sensation of weight and fullness in the right hypochondrium, and pain may be felt in the right shoulder. Jaundice caused by pressure on the bile-ducts, oedema of the legs and scrotum by pressure on the inferior vena cava, and ascites by pressure on the portal vein, may all occur in exceptional cases.

A small cyst may rupture into the biliary passages: intense jaundice results, and the patient generally develops suppurative cholangitis. A large cyst may burst into the general peritoneal cavity, especially after a blow on the abdomen, when shock and collapse may follow. Symptoms of an allergic character may result, especially severe urticaria, erythema and pruritus. Less frequently there may be diarrhoea and vomiting, and dyspnoea, sometimes of an asthmatic character. In rare cases convulsions, collapse and cardiac failure may occur and end fatally. Rupture into the stomach or intestines may lead to spontaneous recovery.

The upper part of the right side of the abdomen and lower part of the thorax become prominent when the cyst is large. If the cyst reaches the front of the liver it becomes palpable in the hypogastrium. When it projects from the under surface, the liver is pushed forward and it may simulate a large gall-bladder or a renal tumour. A cyst near the convexity pushes the diaphragm upwards and may compress the lung and simulate a pleural effusion. In such cases the irregularity in the upper surface of the liver can be recognised with the radiograph. When deeply embedded in the liver, it produces a more general expansion and no local tumour is palpable. The tumour is generally tense and elastic. In rare cases percussion of the middle finger, when the left hand is placed flat over the cyst, produces a peculiar vibration—the hydatid thrill—which is pathognomonic.

Bacteria may invade the fibrous capsule and multiply between it and the cuticular membrane, with the result that the nutrition of the hydatid is impaired and the parasite dies. Its death results in a change in the cuticular membrane, which, when healthy, is impervious to bacteria and leucocytes, but now allows them to pass into the fluid, which acts as an excellent culture medium and gradually becomes filled with pus cells. Symptoms of hepatic abscess are present, and the abscess may finally rupture into the general peritoneal cavity, stomach or intestines.

Diagnosis—The discovery of a tumour of the liver should lead to a consideration of cancer, syphilis and hydatid cyst. The general health is greatly affected in the first, comparatively little or not at all in the second and third. In cancer and syphilis the tumour is likely to be irregular and multiple, in hydatid it is a uniform round swelling, and most frequently only one can be felt. The two former are hard and obviously solid, while the latter is elastic, and in rare cases the characteristic hydatid thrill can be felt. The Wassermann reaction is positive with a gumma and generally negative in the other diseases. Eosinophilia is frequent in hydatid, but in no other liver disease, and may rise as high as 75 per cent. The intradermal injection of sterile hydatid fluid produces a positive cutaneous reaction in 90 per cent of cases (Casoni test). Once the skin has become sensitised it may remain so permanently in spite of removal of the cyst. The complement fixation and precipitin tests are less reliable. Radiography may show the outline of a hydatid cyst if its wall has become partly or wholly calcified.

Prognosis—A cyst may continue to grow for 20 or 30 years, but the possibility of suppuration or perforation is a constant danger. When it dies, the cuticular membrane folds on itself and may become calcified, its contents dry up and form a mass containing gritty material. It can then cause no further trouble.

Treatment—In places where hydatid disease is common, dogs should never be fed on raw offal. They should be treated periodically with the vermifuge, arcoline, and not petted unless the hands are carefully washed afterwards.

Hydatid cysts were formerly treated by tapping, but such methods have now been completely superseded by an open operation, in which the fluid is evacuated and as much of the cyst wall as possible is removed. In some cases the latter is very loosely attached and can be pulled out intact. The operation should be performed whenever a hydatid cyst is diagnosed, even if it causes no symptoms, as there is always a danger of serious complications.

CARCINOMA OF THE LIVER

Ætiology and Pathology.—(a) **PRIMARY GROWTHS**—Primary carcinoma of the liver is found only about once in each thousand necropsies, and primary sarcoma is considerably rarer. Primary carcinoma may be derived from the liver-cells (hepatoma) or, much less frequently, from the bile duct cells (cholangioma), 90 per cent of the former and 50 per cent of the latter occur in cirrhotic livers. Primary cancer occurs in about 7 per cent of patients with cirrhosis, the incidence being many times as great as among patients without cirrhosis. The incidence is very high in the Dutch East Indies owing to the great frequency of non alcoholic cirrhosis among the natives and to a special tendency of this form of cirrhosis to undergo malignant degeneration. It accounts for some 10 per cent of all malignant tumours in some Asiatic countries such as Japan and the Malay States.

Primary cancer of the liver readily invades the portal vein, along which it spreads in both directions from the point of entry, forming a tree like cast of the affected part of the portal system. On section the growth distended vessels give the appearance of a tumour of multicentric origin, and dissemination to other parts of the liver often occurs through the portal system. In 40 per cent of cases extrahepatic metastases are present. Spread by lymphatics may involve glands in the portal fissure, which press upon the portal vein and bile ducts as well as glands elsewhere in the abdomen and chest, and malignant emboli may pass by the hepatic veins to the lungs. The symptoms may be indistinguishable from those of cirrhosis, the liver being normal in size or considerably enlarged. In the latter case, nodules can sometimes be felt on the surface. The spleen is often enlarged, and ascites develops owing to portal obstruction. Pain in the right hypochondrium and jaundice are more common than in uncomplicated cirrhosis.

(b) **SECONDARY GROWTHS.**—Secondary carcinoma of the liver is about thirty times as common as primary carcinoma; it is ten times as common as secondary sarcoma. It occurs most frequently after the age of 50. It is more common in women than men because it frequently follows carcinoma of the breast and female genital organs, and is rare in carcinoma of the lip, mouth and tongue, which are much more common in men than women. The most common seat of the primary disease is the stomach, and then in order the colon, breast and uterus. Cancer of the gall-bladder, extrahepatic bile-ducts and the stomach may invade the liver by direct continuity.

Symptoms.—The liver is almost always palpable, as it is enlarged and abnormally hard. It becomes progressively larger until it may be so enormous that it appears to fill the whole abdomen, the right lobe being generally most affected. It is irregular in shape, and individual nodules of growth are often depressed in the centre—"umbilicated". Deposits may be felt at the umbilicus and in the falciform ligament near the linea alba.

Persistent pain is generally felt in the right hypochondrium and in the back; it may pass to the right shoulder and occasionally down the arm. It is in part due to stretching of the capsule of the liver, especially when it grows rapidly, but the most severe pain is due to perihepatitis, the presence of which can sometimes be confirmed by feeling and hearing a rub. Deep-seated growths may cause no pain throughout the illness.

Progressive and persistent jaundice is present in 50 per cent. of cases owing to pressure on the main bile-ducts within the liver by the growth or on those in the portal fissure by glands. The fæces sometimes retain their colour, as the jaundice may be due to pressure on the intrahepatic bile-ducts, one or more of which escape.

Ascites develops in 50 per cent. of cases, generally as result of malignant peritonitis or perihepatitis. It may also be caused by pressure on the capillaries when the liver is extensively infiltrated with growth and by portal thrombosis following invasion of the portal vein. The fluid is generally serous, and when jaundice is present it is bile-stained. Extravasation of blood into a superficial nodule may cause it to be hæmorrhagic. In rare cases it is chylous owing to obstruction of a main lymphatic, but more frequently it is chyloform. Perforation of the organ primarily involved or infection without perforation may cause it to become purulent. Oedema of the ankles is present in the late stages as a result of toxæmia, hypoproteinæmia and cardiac weakness. More widespread dropsy may be caused by pressure upon or thrombosis of the inferior vena cava or some other large vein.

In the late stages the patient becomes rapidly weaker. The appetite is lost, and there is often a special distaste for meat. The body weight falls progressively, but occasionally the loss of weight due to the general emaciation is more than counterbalanced by the increase in weight of the liver and the accumulation of fluid in the abdomen. The skin is inelastic and sallow, and secondary anæmia develops. It is often possible to see the liver moving up and down with respiration through the wasted abdominal wall. Fever is often present, especially in rapidly advancing cases, quite apart from that caused by infection of the primary growth or of a necrotic secondary deposit. Suppurative cholangitis may be caused by the infection of obstructed ducts.

The large liver and the ascites may push the diaphragm up and compress the bases of the lungs, which are then likely to become congested, but the main enlargement is always downwards. The growth may spread through the diaphragm and cause hiccough and cough; pleurisy generally develops and often gives rise to a blood-stained effusion, but empyema is rare.

Finally the patient becomes somnolent and sometimes delirious. Coma is generally present during the last few days of life. Respiration becomes gradually more shallow, and death comes imperceptibly.

Diagnosis.—A painful, tender and irregular enlargement of the liver is most frequently due to a growth, and the probability is increased if general symptoms of

malignant disease are present. If there is evidence of a primary growth elsewhere or a growth has been removed by operation within the last 5 years, the diagnosis can be made with certainty.

The tumour produced by cancer of the liver must be distinguished from one produced by syphilis and hydatid of the liver. The shape of the liver often helps in the diagnosis, and umbilication of a nodule is conclusive evidence of cancer. The general health is much more impaired and the patient is generally older in cancer than in syphilis and hydatid disease. A history of syphilis or evidence of its effects in other parts of the body points to a gumma, and unless a primary growth is discovered the Wassermann reaction should always be tested. Whenever hydatid disease is possible, a differential blood count should be made, as eosinophilia is frequently present, but not in the other conditions. When there is ascites it may be impossible to diagnose between cirrhosis and cancer, especially if the patient is slightly jaundiced. The abdomen should be tapped so that the liver can be palpated, the irregularities of the cirrhotic liver are so much less marked than those in cancer that they are often not recognisable through the abdominal wall. The spleen is generally large in cirrhosis, but normal in size in cancer, and the liver is rarely very large in cirrhosis. Pain is generally much greater in cancer, and jaundice, when present, is more profound.

In secondary cancer of the liver the primary disease is often latent, especially when it is situated in the stomach, colon, tail of the pancreas, prostate or lung. But when a thorough investigation fails to reveal a primary growth elsewhere in the body, if jaundice and ascites are absent and emaciation is slight, a single, rapidly growing tumour of the liver is more likely to be primary than secondary. In doubtful cases liver puncture may provide a conclusive diagnosis, but an exploratory laparotomy may often be of more value as it enables a biopsy to be done if needed, and satisfies both physician and relatives that no possible further therapeutic steps are possible. Peritoneoscopy, though regularly practised in some clinics, has had little general support as a diagnostic procedure (see p 723).

Prognosis.—Cancer of the liver is always fatal. The course of primary cancer is very rapid, as it rarely lasts more than 4 months, and death may occur even within 4 weeks of the onset of symptoms. The duration of the illness in secondary carcinoma of the liver depends upon the primary disease, death being often due to the latter. If the primary disease has been removed by operation or is latent, death may not occur for a year or even longer after the disease of the liver is discovered, but most cases prove fatal within 6 months. The disease generally advances steadily, but it may remain almost stationary for a time and then rapidly progress to a fatal issue.

Treatment.—It is rarely justifiable to operate when it is known that a growth of the liver is present, but if during an operation for cancer of the stomach or gall-bladder the liver is found to be involved only in its immediate neighbourhood, an attempt should be made to remove the affected part. Moreover, the presence of one or more small nodules in the liver does not contraindicate partial gastrectomy or colectomy for the primary growth, as the operation may be followed by a period of a year or more of complete freedom from symptoms. Much care and thought must be given to the psychological handling of the individual patient, though no general rule can be laid down it is in general, unwise to inform him that he has an inoperable and fatal disease. If it is decided to tell him the truth, some form of treatment should, if possible, be given him at the same time in order to provide some slight hope even if this is plainly stated to be small.

The medical treatment of cancer of the liver is purely palliative, but by means of morphine the patient should be spared pain throughout the illness. An injection of morphine should be given whenever pain is felt and the dose should be increased as the disease progresses and the patient becomes accustomed to the drug. With adequate dosage patients can be kept drowsy but free from pain and not unhappy to the end. The bowels should be kept regular by drugs, the dose of which generally

requires to be increased as more morphine is given. The patient should be allowed to eat and drink exactly what he likes, and no restrictions should be made on account of the supposed indigestibility of certain articles of food, nor should large quantities of food be forced upon a patient who has no appetite. When the diagnosis has once been made with complete certainty, frequent examinations of the abdomen distress the patient without doing any good.

NON-SUPPURATIVE PYLEPHLEBITIS AND PORTAL THROMBOSIS

Ætiology and Pathology—The stagnation of blood caused by cirrhosis of the liver accounts for about 30 per cent. of cases of portal thrombosis, but the latter is so rare that it occurs in less than 5 per cent. of cases of cirrhosis. Malignant disease of the liver, stomach or pancreas is the next most common cause, invasion of the veins of the affected organ leads to thrombosis, which spreads to the portal vein. Syphilitic changes in the walls of the portal vein and non-suppurative pylephlebitis caused by spread of infection from neighbouring parts may cause thrombosis.

Portal thrombosis may extend throughout the vein and its branches, but more frequently it is localised to the main trunk and one or more intrahepatic branches or extrahepatic tributaries.

Symptoms—In the presence of cirrhosis of the liver or intra abdominal growth especially if ascites is present, there may be no indication that portal thrombosis has occurred. If, however, the patient is in comparatively good health, sudden occlusion of the portal vein may lead to the rapid development of ascites, hæmatemesis and melæna, and the spleen becomes enlarged. When the splenic vein is occluded, the splenic enlargement is rapid and considerable. When mesenteric veins are suddenly involved, hæmorrhagic infarction results and leads to intestinal paralysis with severe melæna and early death.

SUPPURATIVE PYLEPHLEBITIS

Ætiology—Suppurative pylephlebitis is almost always secondary to some intra abdominal inflammatory disease, generally associated with the presence of pus under pressure. Acute appendicitis accounts for nearly half of the cases.

Pathology—The veins leading from the source of infection to the liver, together with the trunk and intrahepatic branches of the hepatic vein, may all be involved but the disease is generally less extensive and may be confined by firm clots to a part of the portal vein or one of its branches. The affected veins contain pus and broken-down blood clots. Their walls are acutely inflamed and may give way, leading to the formation of abscesses. Thus a large abscess may develop in the mesentery or behind the pancreas. The liver is almost always involved by extension to the intrahepatic portal branches or by secondary abscesses formed from infective emboli from the part of the vein primarily affected. Innumerable minute abscesses are present, many of which may coalesce to form a honey-combed appearance or large abscesses. Superficial abscesses may rupture and lead to general or local peritonitis which may also result from the primary disease. The infection is generally caused by *Bact. coli*, streptococci or staphylococci, and very rarely by *Salmon typhi* or *Sh. dysenteriae*.

Symptoms—The onset is generally sudden, the symptoms due to the primary disease being complicated by the occurrence of a rigor or pain and tenderness over the liver. The clinical picture is eventually a composite one of the symptoms of the primary disease, sepsis and liver disease, with the frequent addition before death of

pneumonia, pulmonary abscesses or empyema, generally on the right side. Evidence of portal obstruction is rarely present. The patient looks anxious and ill. He is sallow and in about half the cases is slightly jaundiced. Fever is continuous, intermittent or remittent, leucocytosis is present, and the pulse and respiration are rapid. Rigors with profuse sweating are common, especially in the early stages. Uniform enlargement of the liver occurs in about 60 per cent of cases. Pain and tenderness are generally present, and a rub may be heard over the liver. The spleen is only occasionally enlarged. Vomiting is common and diarrhoea may occur. Blood cultures are generally sterile.

Diagnosis.—The development of a septic state with rigors and enlargement and tenderness of the liver in a patient with appendicitis or other intra-abdominal disease is suggestive of suppurative pyelephlebitis, but a correct diagnosis is rarely made. In anæmic abscess of the liver there is generally a history of dysentery, the progress of the disease is less rapid, and there may be signs of a single abscess instead of a uniform enlargement of the liver. A history of gall stones is much more common in suppurative cholangitis than in pyelephlebitis, and jaundice appears earlier and is deeper. The diagnosis from a sub diaphragmatic abscess secondary to appendicitis may be impossible, and the two may be present together. Acute infective endocarditis with enlargement of the liver and spleen without cardiac murmurs closely simulates suppurative pyelephlebitis.

Prognosis and Treatment.—The disease is almost always fatal, and no treatment is of real avail, though massive doses of antibiotics and sulphonamides should always be tried.

THOMAS HUNT

DISEASES OF THE GALL-BLADDER AND BILE-DUCTS

CHOLECYSTITIS

Ætiology and Pathology.—Cholecystitis results from infection of the gall-bladder most frequently with *Bact coli*, but also with *Salm typhi* and *paratyphi*, streptococci and staphylococci. The mere presence of bacteria in the bile does not necessarily lead to cholecystitis, just as bacilluria may occur without causing pyelitis. Organisms which normally inhabit the colon and lower part of the ileum might theoretically gain access to the gall bladder by four different channels.

(1) Typhoid bacilli pass from the intestines by the lacteals to the mesenteric glands, from which they are conveyed by the lymphatics to the thoracic duct and thence into the general circulation, a typhoid septicæmia being thus produced. The bacilli are excreted from the blood into the bile by the liver and in the urine by the kidneys probably in every case, but cholecystitis and pyelitis develop in only a comparatively small proportion. There is no doubt that *Bact coli* can pass through the healthy bowel wall, but under ordinary conditions it reaches no farther than the lymphatic glands, which act as a very efficient filter, and there is no evidence that cholecystitis is ever preceded by a *Bact coli* septicæmia.

(2) The portal vein would seem a likely channel for the passage of *Bact coli* to the liver and thence in the bile to the gall bladder without gaining access to the general circulation. But the portal blood is normally sterile and remains so even when the wall of the bowel is damaged, and bacteria injected into the portal vein of animals are not excreted in the bile.

(3) It has been suggested that cholecystitis is the result of infection with strains of streptococci having a special affinity for the gall-bladder, which are conveyed to

it by the cystic artery from infected teeth, tonsils and other foci. But infection of the gall-bladder with streptococci is much less common than with *Bact. coli*, and later investigations have failed to confirm the experiments upon which this theory was based.

(4) Cholecystitis might be due to an ascending infection from the duodenum, and though this is normally sterile, in achlorhydria large numbers of *Bact. coli* and streptococci are often present, and achlorhydria is found in about 30 per cent. of cases of gall-stones. In the acute gastritis which occurs in food poisoning and influenza and other infections achlorhydria is generally present, and it is possible therefore that the duodenum may be infected during the temporary achlorhydria resulting from acute gastritis, and last sufficiently long for ascending infection of the gall-bladder to occur. It is in fact not uncommon for patients with chronic cholecystitis to date their symptoms from an attack of food poisoning or an acute infection, which may have been accompanied by achlorhydria, even if the gastric secretion when the patient comes under observation is normal.

Infection of the gall-bladder first leads to inflammation of the mucous membrane, the external appearance of the gall-bladder remaining normal. The inflammation subsequently spreads to the deeper tissues; the walls become thick and inelastic and the cystic lymphatic gland enlarged and inflamed.

Cholecystitis may be acute, subacute or chronic from the onset. Acute and subacute cases may become chronic, and suppuration or gangrene may occur in a chronically inflamed gall-bladder if a stone becomes impacted in the mouth of the cystic duct. The contents may become purulent in the course of an acute infection without gall-stones, but necrosis is very rare in their absence.

ACUTE CHOLECYSTITIS; EMPYEMA OF THE GALL-BLADDER

Ætiology and Pathogenesis.—Acute cholecystitis occurs in about 1 per cent. of cases of typhoid and paratyphoid fever. Apart from this it is rare unless the cystic duct is obstructed by an impacted gall-stone. Bile is generally present in the gall-bladder only if the contents are examined within a few days of the onset. The wall is thickened and obviously inflamed, and the cystic lymphatic gland is enlarged. When the cholecystitis is secondary to an impacted gall-stone suppuration or gangrene is likely to occur. Suppuration leads to empyema of the gall-bladder: if adhesions have previously formed as a result of chronic cholecystitis the empyema may rupture into the duodenum or colon; otherwise localised or generalised peritonitis results. Necrosis may be localised or general. When localised it is generally secondary to ulceration at the neck of the gall-bladder following impaction of a stone; rupture into the duodenum or the production of a local abscess commonly follows. The whole wall of the gall-bladder may become gangrenous as a result of over-distension from obstruction of the cystic duct or less commonly of the common bile-duct, especially in elderly people in whom the blood supply is deficient; unless cholecystectomy is promptly performed, general peritonitis is then certain to develop.

Symptoms.—Acute pain in the right hypochondrium is the most constant symptom. It often radiates to the angle of the right scapula and less frequently to the right shoulder. The gall-bladder may be felt as an extremely tender tumour, but more frequently the rigidity of the right rectus makes deep palpation impossible. Jaundice occurs only if there is a stone in the common bile-duct or the cholecystitis is part of a general infection of the biliary passages. Pyrexia with polymorphonuclear leucocytosis is always present.

The *defense musculaire* often involves the right dome of the diaphragm as well as the right rectus, and signs of œdema and congestion of the base of the right lung may be present.

In mild cases recovery takes place after a few days, but symptoms of chronic

cholecystitis may develop at a later date. In suppurative or gangrenous cholecystitis fatal complications rapidly occur unless an early operation is performed.

Treatment.—The patient should be kept strictly at rest with a lacto-vegetarian diet and the local application of heat. The effect of sulphonamides and full doses of antibiotics should be tried but if suppuration or gangrene is suspected, an operation should be performed without delay.

CHRONIC CHOLECYSTITIS

Symptoms.—Chronic cholecystitis is a common cause of chronic dyspepsia. The patient complains of intractable indigestion of an irregular character, in striking contrast with the clock-like regularity of the pain in duodenal ulcer. The time of onset and the severity of the pain vary greatly from meal to meal and from day to day; it sometimes begins immediately after food, and at other times it may not come until 2 or 3 hours after a meal, or it may occur only in the early part of the night. It is unaffected or only incompletely relieved by taking food and by alkalis. In most cases the patient complains of what he calls flatulence, but this is really only a sensation of fullness, which is not associated with increased fermentation, and with eructation only when it gives rise to aerophagy by causing the patient to make repeated but futile efforts to belch in the hope of relieving his discomfort.

Nausea is common. It may occur on waking, when it is sometimes associated with vertigo, cold sweats or headaches, in which case migraine may be simulated, though the headache is not unilateral. It may be relieved by breakfast, unless eggs are eaten, when it is often aggravated. It is sometimes followed by vomiting, which gives much less complete relief than in ulcer.

Patients with ulcer generally lose all their pain in 2 or 3 days if put to bed on a strict diet, but improvement is less likely to follow in cholecystitis; the dyspepsia may, however, rapidly improve if fried food and other indigestible fatty foods are prohibited. Constipation is generally present, but in some cases intermittent or continuous diarrhoea of a mild grade occurs, and in rare instances profuse, watery diarrhoea heralds the onset of an acute exacerbation.

If attacks of biliary colic, whether of the abortive or acute variety, occur in association with symptoms of cholecystitis, gall-stones are probably present.

The discomfort after meals is generally in the mid-epigastrium, but it often extends to the right and may be confined from its onset to the right hypochondrium. It is frequently associated with pain at the angle of the right scapula.

Tenderness of the gall-bladder is the most characteristic sign of cholecystitis. It is best elicited with the patient lying relaxed on his back; the fingers are then pressed beneath the right costal margin in the region of the gall-bladder. The pain is much increased when the fingers are brought into still more intimate contact with the gall-bladder by deep inspiration, which is then sharply arrested.¹ The pain produced in this way is in striking contrast with the absence of tenderness when deep pressure is exerted under the left costal margin or a short distance to the inner or outer side of the gall-bladder under the right costal margin, though it is not uncommon for a slighter degree of tenderness to be observed over the whole of the lower border of the liver, especially in the immediate neighbourhood of the gall-bladder. Pressure on the gall-bladder may also cause nausea.

The upper part of the right rectus abdominis muscle is often tender and rigid; tenderness and rigidity of the lowest intercostal muscles may cause impeded respiration and a stitch in the right side of the chest. Tenderness is also sometimes present over the third to the tenth dorsal spines, the muscles to their immediate right and the end of the eleventh rib.

¹ This sign was first described by Naunyn in 1892, but is often incorrectly ascribed to Murphy who described it ten years later.

In chronic cholecystitis there is generally no pyrexia, but occasionally the temperature rises to between 99° and 100° F each evening or during exacerbations of the inflammation accompanied by more marked symptoms. Jaundice rarely occurs unless there is biliary obstruction due to a calculus, but in some cases an associated hepatitis leads to slight icterus and marked excess of urobilinogen in the urine.

Diagnosis—The healthy gall bladder can be visualised by cholecystography. After a preliminary film of the right upper quadrant of the abdomen has been taken, a dose of pheniodol or Telepaque is swallowed in the evening and no further food or drink is taken until the next morning. Films are then taken at 12 to 16 hours after swallowing the dye and, if no good shadow is seen, again at 18 and 20 hours. When a sufficiently clear picture has been obtained a fatty meal, consisting mainly of buttered eggs is eaten and films are taken at hourly intervals to show the gall bladder contractility and rate of emptying. If no shadow is seen at all, the test is repeated the next day using a slightly larger dose of the radio opaque dye. Pheniodol and similar compounds have now in general replaced the earlier tetraiodophenol phthaleine first used by Graham and Cole in 1924. Most of the substances now used contain over 60 per cent of iodine and are contraindicated in renal disease and in gastro intestinal disorders such as pyloric stenosis, which prevent absorption from the alimentary tract. Liver disease need not be regarded as a contraindication. The method depends upon the substance used containing atoms of sufficient atomic weight to throw a radiographic shadow, and upon its proper absorption in the alimentary tract and secretion into the bile by the liver. In this way it reaches the gall bladder via the cystic duct where, as a result of absorption of nine tenths of the water of the bile by the mucous membrane, it becomes sufficiently concentrated to throw a shadow of the gall bladder, which can be seen on the screen, and a cholecystograph taken. A normal gall bladder gives a homogeneous shadow with a regular outline, it is not tender when directly palpated, and it is freely movable, being quite independent of the shadow of the duodenal bulb which can be seen simultaneously by giving a small opaque meal. The normal gall bladder is found to have contracted and evacuated the greater part of its contents an hour after the fatty meal. If no shadow of the gall bladder is obtained this may be due either to the dye not having entered the gall bladder or to its not being concentrated by it sufficiently to give a radio opaque shadow. The former may occur in liver disease, especially if jaundice is present, or if a calculus or adhesions obstruct the neck of the gall bladder at the cystic duct, and the latter if the mucous membrane of the gall bladder is unable to concentrate the bile—as in cholecystitis—whether gall stones are present or not. Variations in shape, position and density of shadow and emptying after a fatty meal are difficult to interpret, but may indicate cholecystitis, when the mucous membrane is at all seriously diseased no shadow is seen. In some cases of cholecystitis the visualised gall bladder is tender, or may be in an unusual position or deformed by adhesions even when contracted after the fatty meal, it may then be impossible to separate the shadow of the gall bladder from that of the duodenal bulb. It must be pointed out however, that poor technique in radiography, bad preparation of the patient, vomiting of the dye overlying gas shadows, and a few rare congenital abnormalities all make the interpretation of cholecystograms a matter requiring considerable experience.

When the diagnosis is uncertain, an attempt may be made to obtain some of the contents of the gall bladder for pathological examination. A sterilised duodenal tube is swallowed up to the 23 in mark first thing in the morning before the patient has had anything to eat or drink. The stomach is emptied and washed out with sterile water. The tube is then slowly paid out up to the 28½ in mark, which allows sufficient length for the duodenum to be reached. Samples are aspirated periodically until the comparatively abundant acid turbid and colourless fluid present in the stomach is replaced by the very small quantity of neutral or alkaline, clear and generally bile stained fluid present in the duodenum, which generally occurs within 1 or

2 hours Radiographic control of the position of the tube is advisable, if means are available. The duodenum is washed out with sterile water, and 25 ml of a 25 per cent solution of magnesium sulphate are injected through the tube. This causes the gall bladder and the bile ducts to contract and the sphincter of the common bile duct to relax. An abundant flow of pure bile, first pale from the common bile duct and then dark from the gall-bladder, rapidly appears. This is aspirated, and the tube is withdrawn. In the absence of disease the gall bladder bile contains no pus cells, and only a few epithelial cells, pigment granules and rarely cholesterol crystals; it is generally sterile, but a few bacteria may be present if the duodenum has not been sufficiently washed out, especially in cases of achlorhydria. In cholecystitis the quantity of mucus is greater than normal, and degenerated columnar epithelial cells, pigment granules and less frequently, pus cells are present; the bile contains bacteria, most commonly an aberrant form of *Bact. coli* in pure culture, and rarely streptococci or staphylococci. In rare cases *Salmonella typhi* may be isolated many years after the original typhoid fever. The combination of cholesterol crystals with pigment granules suggests the presence of gall-stones, especially if large cholesterol crystals with the corners broken or rounded are found.

Treatment—Some early cases of cholecystitis can be cured by medical treatment, and great improvement often occurs even in very chronic cases. Sulphonamide drugs are excreted in the bile in a concentration sufficient for bacteriostatic effects as judged by the levels required for this purpose in the blood. Unfortunately, since they reach the gall bladder via the cystic duct and not through the blood stream, they are not excreted in the bile in significant amounts if either liver disease or cystic duct obstruction is present. The same applies to both penicillin and streptomycin, nevertheless a trial of chemotherapy is justified provided there is no clear evidence of either of these complications and good results may certainly follow a course of sulphadiazine in a few cases. There is some evidence that part of this drug may reach the gall bladder wall directly through the blood.

Hexamine has been widely used as a biliary disinfectant and must be given with alkalis to avoid risk of damaging the kidneys. It is excreted unchanged in the bile and is given in doses of gr. 60 increasing up to gr. 120 with an equal amount of sodium bicarbonate. It must be taken on an empty stomach and should not be followed by food which will cause the gall bladder to empty itself rapidly. Daily treatment must be continued for a number of weeks but results are difficult to assess.

Biliary drainage should be stimulated by giving a concentrated solution of magnesium sulphate when the stomach is empty an hour before breakfast. The correct dose is the largest quantity the patient can take without producing diarrhoea when no other aperient is used. The salts cause the gall bladder and bile ducts to empty their contents into the duodenum through the relaxed sphincter of the common bile duct. Half an ounce of olive oil should be taken three times a day half an hour before meals as it has the same effect as magnesium sulphate on the gall bladder. Bile salts are the most effective of all stimulants of bile excretion and they also play an essential part in keeping cholesterol in solution. The sodium salt of dehydrocholic acid (Dehydrocholin) should be given three times a day in a dose of gr. 3 to 5.

There is no clear evidence that food containing cholesterol has any appreciable effect on the quantity of cholesterol in the blood or bile. Consequently a cholesterol free diet cannot be regarded as a means of preventing gall stones. When however, a patient with cholecystitis is aware that the less digestible forms of fatty food give him discomfort, they should of course, be avoided. If, however, he is able to tolerate fats they should be included in the diet, as they stimulate gall bladder emptying.

If achlorhydria is present gastric lavage may be practised in the hope that normal secretion will be restored and hydrochloric acid should be given before breakfast and with lunch and dinner.

The only indication for surgery in chronic cholecystitis is the failure of medical

treatment which has been thoroughly carried out for an adequate time. If it is likely that gall-stones are present, it is generally useless to delay operation. In all cases cholecystectomy should be performed in preference to cholecystostomy.

GALL-STONES

Synonym.—Cholelithiasis.

Ætiology.—Clinically gall-stones occur about twice as frequently in women as in men, but they are found post mortem about five times more often in women than men. They are very rare before the age of 15; 75 per cent. of clinical cases occur between 30 and 60, 40 to 45 being the most common age. The incidence is greatest post mortem about 20 years later. Gall-stones occur in about 20 per cent. of all women and 7 per cent. of all men dying after the age of 25. There is a definite tendency for gall-stones to be familial, and they are often associated with obesity and overeating.

Pathology.—(a) *Infection.*—Infection of the gall-bladder leads to cholecystitis. The agglutinated bacteria, precipitated mucus and cellular debris may form the nucleus of gall-stones if excess of cholesterol or bile-pigment is present in the bile, especially if the flow from the gall-bladder is less free than it should be. The nature and the path of infection have been discussed in connection with cholecystitis (p. 689). Stones may form very rapidly, but when they have once formed, the infection frequently dies out, and the bile, stones and wall of the gall-bladder may be sterile, though the latter still shows signs of old inflammation. In other cases the organisms commonly found in cholecystitis are still present. The "strawberry gall-bladder" is probably the result of low-grade infection. In this condition, also called cholesterolosis of the gall-bladder, cholesterol esters are formed in the wall of the gall-bladder and appear on the inner surface as multiple yellowish granules visible to the naked eye giving, on the congested and reddened mucous membrane, the appearance of an unripe strawberry.

(b) *Excess of cholesterol in the blood and bile.*—The majority of gall-stones contain a considerable proportion of cholesterol. Normal blood contains cholesterol, which comes from endogenous and exogenous sources. The endogenous cholesterol is produced by the constant activity of the cortex of the suprarenal glands, and by the periodic activity of the corpus luteum at each menstrual period. During pregnancy the corpus luteum produces a very large quantity of cholesterol, so that the percentage in the blood gradually increases to nearly double and that in the bile to four times the normal. The exogenous cholesterol comes from certain articles of diet; it is abundantly present in eggs and to a less extent in cream, and in liver, kidney, sweetbread and brain. The importance of hypercholesterolaemia in the pathogenesis of gall-stones has, however, been exaggerated. Accurate post-mortem statistics show that the greater incidence of gall-stones in females is not due to pregnancy, as the proportion of women with gall-stones who have borne children to those who have not is the same as the proportion among those who have no gall-stones. But there is no doubt that a biochemical factor must be present to explain the development of the large, solitary, pure cholesterol stones, which are occasionally found in perfectly healthy and sterile gall-bladders, and it is probable that some constitutional peculiarity in connection with cholesterol metabolism is an important predisposing cause.

(c) *Biliary stasis.*—A stone is especially likely to form in the presence of infection and excess of cholesterol in the bile if biliary stasis is also present. In some cases there appears to be a congenital or acquired abnormality of the anatomical relations or of the neuro-muscular mechanism of the bile channels, which impedes the evacuation of the bile (see p. 661). Deficient exercise also leads to biliary stasis.

By examining sections of gall-stones it is generally possible to get some idea of

the history of their formation. Thus the centre of most is white and consists of pure cholesterol; only after the stone has reached a certain size is there, as a rule, any deposit of pigment and lime salts resulting from a period of infection. Then there may be a further layer of cholesterol caused by hypercholesterolaemia, possibly the result of pregnancy; then another stratum of pigment and lime salts may form, and so on. A pure cholesterol stone corresponds to a pure oxalic acid or uric acid stone in the kidney, and the presence of pigment and of lime salts corresponds to that of phosphates in a urinary stone. Pure pigment stones are frequently found in cases of acholuric jaundice, when they are secondary to excessive production of bile-pigment by hæmolysis.

Symptoms.—Gall-stones may be completely latent. More frequently their development is preceded and accompanied by continuous or intermittent dyspepsia. These "inaugural symptoms" are sometimes referred to as gall-stone dyspepsia: they are really due to cholecystitis (pp. 690, 691) and not to the presence of stones. Abortive attacks of biliary colic may occur independently of or associated with gall-bladder dyspepsia. Typical attacks of severe colic are less frequent and are uncommon in the absence of previous symptoms.

Many patients who suffer from gall-bladder dyspepsia and a few who have no such symptoms complain of short attacks of severe pain, which may occur at any time of the day or night with or without any obvious cause, such as an indiscretion in diet: occasionally an attack is the direct sequel of a long railway journey, a drive in a motor car on a bad road, or violent exercise. Attacks may occur daily or at long intervals, or there may be a series close together followed by a long spell of freedom. The patient may shiver during an attack, although his temperature never rises greatly and often does not rise at all. When the pain is acute, it is impossible to take a deep breath, the attempt producing a "catch" in the right side of the chest, which is very similar to that felt in pleurisy.

Attacks of biliary colic most frequently result from impaction of the stone in the neck of the gall-bladder close to or at its junction with the cystic duct. They often occur in the night. The attack begins with extremely sudden acute pain high in the epigastrium or in the region of the gall-bladder or both; it may pass through to the angle of the right scapula; it is often continuous and not of colicky type. The violent pain is accompanied by great restlessness, in contrast to the motionless state of a patient with a perforated ulcer or acute appendicitis. Some relief may be obtained by pressing upon the abdomen. The patient feels cold, but sweats profusely. Slight inspiratory distress is common, but the presence of definite dyspnoea or faintness, when the pain is high in the epigastrium or still more so if it is substernal, should raise the suspicion of coronary thrombosis as an alternative diagnosis. Nausea almost always occurs; the presence of vomiting generally indicates that the stone has passed from the gall-bladder into the cystic or common bile duct. Aerophagy is generally present. The pain commonly disappears with absolute suddenness. The sudden onset and sudden cessation are specially characteristic of gall-stone obstruction in the cystic duct. The temperature may rise a degree or two during the attack, and there may be a slight temporary leucocytosis. Constipation is complete.

Jaundice occurs only when a stone reaches the common bile-duct. Repeated attacks without jaundice are generally caused by a stone of some size becoming impacted in the neck of the gall-bladder. Repeated attacks with jaundice, which may be very evanescent and sometimes completely latent and only recognisable by a temporary rise in the serum bilirubin indicate the passage of small stones down the cystic and common bile-ducts into the duodenum, numerous stones being generally still present in the gall-bladder. The slightest yellow tinge of the conjunctivæ or a trace of bile in the urine is strong evidence that an attack of pain of doubtful origin is due to gall-stones.

If a small stone, having traversed the cystic duct and passed down the common

bile duct to reach the ampulla of Vater, remains there owing to the smallness of the lumen of the sphincter, a special group of symptoms appears. In two thirds of the cases one or more stones are still present in the gall bladder. A stone in the ampulla acts as a ball valve causing intermittent attacks of colic with incomplete jaundice. Pain is variable, it is occasionally the only symptom. Vomiting is common in the attacks, which are accompanied by fever with chills or severe rigors in 50 per cent. of cases. The jaundice is rarely complete and persistent, it is occasionally absent, but in such cases serum tests generally show that hyperbilirubinæmia is present, in rare cases it is unaccompanied by pain. In the intervals between attacks the patient may appear to be quite well, though a slight degree of jaundice or some residual pain in the gall-bladder region may be present. Sooner or later ascending cholangitis is likely to develop, there is then constant pyrexia with repeated rigors and polymorphonuclear leucocytosis. If the condition is of long duration, the liver becomes enlarged and hard as a result of biliary obstructive cirrhosis, the spleen is palpable in about one third of the cases.

Small gall stones are rarely recognised in the stools and larger ones are very rarely passed. It is important to distinguish gall stones from concretions produced by drugs or by the administration of large quantities of olive oil. The majority of gall stones consist of cholesterol and can, therefore, be recognised by being very light and inflammable. The rarest form of stone to be passed is a very small rounded one, which has probably traversed the normal passages during an attack of colic, as it may be the only one, a cure may result. More frequently faceted stones are passed, even if large numbers are found, it is very unlikely that all have left the gall-bladder. Lastly one, or less frequently two or three large stones, which may be formed by the agglomeration of several smaller ones, may be passed after traversing a fistulous communication between the gall bladder and duodenum or colon. The fistula may develop very slowly without symptoms after chronic cholecystitis has led to the production of adhesions. More frequently the perforation appears to be sudden and takes place during or after an attack of colic. In other cases the fistula may be caused by the perforation of an empyema of the gall bladder into the bowel. In rare cases a large stone may cause acute intestinal obstruction, generally near the end of the ileum. Occasionally the pain in the neighbourhood of the umbilicus or the right iliac fossa disappears spontaneously as the stone passes onwards, pain may be subsequently felt below the umbilicus and finally in the rectum, from which the stone may have to be dislodged by the finger. The complete passage may take from 1 to 8 days.

It is generally impossible to palpate the gall bladder during an attack of acute pain owing to the rigidity of the abdominal muscles but when the attack passes off the tenderness generally becomes localised to the gall bladder itself. In some early cases the gall bladder is found to be enlarged owing to distension with clear fluid, especially if the stone is impacted in the cystic duct. It gradually contracts on the stone or stones within it, probably after temporary dilatation, so that in long standing cases it is rarely palpable. Even if a gall-stone passes into the common bile duct, the gall bladder does not often become enlarged, thus a large gall bladder in a case of chronic jaundice generally indicates chronic pancreatitis or a growth of the head of the pancreas or of the common bile duct, rather than stone (Courvoisier's law).

Pure cholesterol gall stones are never visible with the radiograph but when lime salts are present, especially in thin patients they often throw a characteristic "ring" shadow. The shadow must be distinguished from that produced by a renal calculus, a calcified tuberculous focus in a kidney, a calcified tuberculous gland or a calcareous deposit in a costal cartilage. This can be easily done by means of cholecystography. This method also makes it possible to photograph transparent stones, as they may then appear as pale areas surrounded by the dark shadow formed by the dye filling the rest of the gall bladder. Failure to visualise the gall bladder on two successive

occasions, especially in the presence of a good shadow of the liver, which proves that the dye has been absorbed from the intestines, indicates that the cystic duct is obstructed, probably by an impacted stone, that the lumen of the gall bladder is entirely occupied by stones, or that its mucous membrane is so damaged that it is incapable of absorbing water and so producing the concentration of the bile necessary for the production of a shadow.

In doubtful cases valuable information can often be obtained by examination of the bile obtained through a duodenal tube (p 692). Failure to obtain dark bile on injecting magnesium sulphate would confirm a diagnosis of gall stones suggested by absence of a gall bladder shadow after cholecystography.

Complications—Cholecystitis is always present before gall stones develop, except with the rare solitary sterile cholesterol stone. If the mouth of the cystic duct becomes obstructed suppuration or gangrenous cholecystitis may develop (p 690). In some cases inflammation may spread up the hepatic ducts or down the common bile duct, in the latter case the pancreatic ducts may become infected and chronic pancreatitis develops. In rare cases glycosuria or actual diabetes follows. Primary cancer of the gall-bladder makes up not more than 1 per cent of all cancers, but between 5 and 10 per cent of people over 40 with multiple faceted gall stones ultimately develop cancer of the biliary tract. It is probable that it is the chronic cholecystitis which is associated with the carcinoma rather than the gall stones since the relationship does not appear to exist in the case of single metabolic cholesterol stones. Biliary fistulae may develop between gall bladder and duodenum or colon, or peritonitis may result from perforation of the gall bladder into the abdominal cavity.

Diagnosis—Gall bladder dyspepsia must be distinguished from that due to peptic ulcer. An onset of duodenal ulcer symptoms after the age of 45 and especially in a woman, is much in favour of gall stones and relief from food and alkalis is rarely as definite in gall stones as in ulcer. Symptoms due to colon spasm and constipation often cause difficulty in diagnosis, especially as a spastic colon and cholelithiasis often exist together in the same patient. The pain of coronary infarction is usually sub-sternal and often spreads to the neck and arms, but may be exceedingly difficult to distinguish from that of gall stones. The distinction from other forms of colic—renal or intestinal—is usually not difficult. When gall stones are associated with persistent jaundice the diagnosis from hepatitis, carcinoma of the head of the pancreas or cirrhosis of the liver may be very difficult, loss of weight occurs in all four, but a distended gall bladder in the presence of jaundice almost always means a growth. The biliary obstruction due to growth is complete whilst that due to stone is often only partial and frequently intermittent.

Treatment—During an attack of biliary colic the pain should be controlled by the injection of morphine (gr $\frac{1}{2}$) with atropine (gr $\frac{1}{60}$). Slight attacks may be relieved by 1 or 2 tablets of glyceryl trinitrate (gr $\frac{1}{100}$) placed under the tongue. The latter experimentally relaxes spasm of the sphincter of Oddi whilst morphine increases it, but in practice the latter is always effective if enough is given whilst nitroglycerine often fails.

The early recognition and thorough treatment of cholecystitis can be regarded as a true method of prophylaxis of gall stones and attention to obesity, exercise and drug treatment especially with bile salts, as given on p 693 is often successful in relieving dyspepsia and preventing colic.

However if the symptoms point definitely to the presence of gall stones and especially if repeated attacks of biliary colic have occurred, surgery should be advised unless on account of obesity or renal or cardiac complications the patient is too bad a subject for operation. Myocardial disease is not however a contraindication, as the cardiac condition frequently improves after cholecystectomy and patients with impaired hearts often stand the operation remarkably well. Fat patients should be strictly dieted for 2 or 3 months in order to bring their weight down before

operation. If there is evidence of active cholecystitis preliminary treatment with one of the sulphonamide drugs is advisable. The liability to complications or the recurrence of symptoms is reduced by the regular use of magnesium sulphate to prevent stagnation of bile after the operation. Whenever feasible cholecystectomy should be performed in preference to cholecystostomy, and the common bile-duct should always be explored for stones even if there has never been any jaundice. Pre-operative preparation of the patient is of supreme importance and a high protein diet, extra glucose and treatment with vitamin K are measures which do much to lessen risks of operation. The operative mortality for uncomplicated cases in experienced hands is less than 2 per cent.

BILIARY COLIC WITHOUT GALL-STONES

It occasionally happens, especially in otherwise healthy young adults of both sexes, that typical attacks of slight or severe biliary colic, generally unaccompanied by jaundice, occur in the absence of gall-stones. During an attack and for a short time afterwards the gall-bladder is tender. The bile obtained through a duodenal tube from the gall-bladder is normal in every way. Cholecystography occasionally reveals some abnormality in the cystic duct in the form of acute angulation with or without dilatation of the proximal segment, and pressure upon the visualised gall-bladder, especially in a direction from its vertex towards its neck, causes pain; the gall-bladder is sometimes unusually large.

On abdominal exploration the gall-bladder looks healthy, but it may be tightly distended. Examination may show some abnormality in the anatomy of the cystic duct, or an accessory cystic artery may be present, which might cause kinking when the gall-bladder is in certain positions. The condition is analogous to Dietl's renal crises. Cholecystectomy in such cases is sometimes followed by permanent cure, even though neither macroscopical nor microscopical examination shows any abnormality in the gall-bladder wall or contents.

When no anatomical abnormality is discovered, the condition is comparable to that which gives rise to attacks of biliary colic after cholecystectomy for gall-stones or cholecystitis, and which leads to the assumption that a stone has been left in the common bile-duct, though at operation no stone or other cause of organic obstruction is discovered. The attacks are probably due to spasm of the sphincter of the common bile-duct, and are often called biliary dyskinesia. When the gall-bladder has been removed, the common bile-duct often dilates to form a reservoir, which to some extent takes its place, and it may take a long time for the neuro-muscular mechanism of the common duct and its sphincter to adapt itself to the conditions present after cholecystectomy; during this period attacks of pain may result from temporary obstruction by the closed sphincter when the dilated common duct is unable to empty itself.

Diagnosis.—This condition must be considered when attacks of biliary colic are associated with definite tenderness of the gall-bladder, cholecystography shows that no stone is present, and the bile obtained from the gall-bladder is normal. Between attacks the tenderness over the gall-bladder disappears, whereas in cholecystitis it rarely goes completely. The condition is most frequent in nervous and anxious individuals and may be associated with general symptoms of nervous origin. When attacks of colic occur after cholecystectomy has been performed for gall-stones, one or more stones has probably been left in the bile-ducts, but spasm of the sphincter is a possible alternative diagnosis, and treatment for this should be tried before advising further surgery.

Treatment.—Regular contraction of the gall-bladder and ducts and relaxation of the sphincter can be promoted by giving magnesium sulphate when fasting in the

morning and olive oil half an hour before meals. Before resorting to morphine, an attempt to relieve attacks with 1 or 2 glyceryl trinitrate tablets (gr. $\frac{1}{100}$) placed under the tongue should be tried. If attacks persist laparotomy should be advised, the bile-ducts explored and the sphincter of Oddi dilated. A fibrous stricture may be found or the sphincter much hypertrophied. If all the findings at operation are fully normal to the naked eye it is usually unwise to remove the gall-bladder.

CARCINOMA OF THE GALL-BLADDER

Carcinoma of the gall-bladder is a rare disease, which occurs three times more often in women than in men, and generally after the age of 50. Calculi are present in about 75 per cent. of cases (p. 697).

Symptoms.—In about 50 per cent. of cases there is a long history of repeated gall-bladder attacks. This is followed by a short phase of constant pain, accompanied by progressive weakness, anorexia and loss of weight, but no anæmia. The pain is situated in the right hypochondrium and often radiates to the right scapular region. Flatulence, nausea and vomiting are common. A tumour can generally be felt; it may at first be smooth, but later becomes hard and irregular. It is generally not very tender, and there is less muscular rigidity over it than is commonly the case with an inflamed gall-bladder.

After a time secondary deposits lead to symptoms, and in some cases these are most prominent throughout, the primary disease remaining latent. Thus the liver is often large, hard and irregular and jaundice may occur as a result of extension to the bile-ducts or compression by enlarged glands; it is occasionally remittent or intermittent, when it is generally due to cholangitis or a gall-stone in the common bile-duct.

Ascites is present in about a quarter of the cases as a result of malignant peritonitis or pressure of glands on the portal vein. Septic complications, such as suppurative cholecystitis or cholangitis, or local or general peritonitis, may occur. Death generally supervenes within 6 months of the development of definite symptoms apart from those due to the preceding cholecystitis or gall-stones.

Diagnosis.—The diagnosis is often exceedingly difficult, but the presence of a hard irregular tumour in the region of the gall-bladder with pain, anorexia and loss of weight in a middle-aged or elderly individual, especially if there have been symptoms pointing to cholecystitis or gall-stones, is suggestive of a growth of the gall-bladder.

Treatment.—It is rarely possible to remove a growth of the gall-bladder owing to the difficulty in making an early diagnosis. The operative mortality is high, and a very large proportion of cases recur within 6 months. The presence of early carcinoma is occasionally discovered on microscopical examination of a gall-bladder removed on account of chronic cholecystitis with or without gall-stones; permanent recovery may then follow.

CONGENITAL OBLITERATION OF THE BILE-DUCTS

Ætiology.—This rare disease occurs rather more frequently in male than female infants. It is occasionally familial and is not associated with congenital syphilis.

Pathology.—Some unknown toxin probably passes from the mother by the umbilical vein to the fœtus. Part of the toxin reaches the liver direct and causes multilobular cirrhosis. The rest passes into the general circulation and reaches the liver by the hepatic artery; it is excreted in the bile and gives rise to unilobular cirrhosis and inflammation of the small and large ducts and gall-bladder, which, being extremely small at birth, become more or less completely obliterated. The

disease is thus a combination of portal and biliary cirrhosis with obstruction of the ducts.

Symptoms.—Jaundice is generally present at birth, but may not appear for 2 or more weeks. The meconium is normal, but the stools are free from bile from the first, and the urine is deeply bile-stained. The liver and spleen are large and hard. The infant is often remarkably well till the terminal stage, when deficiency in vitamin K results in purpura and hæmorrhages from the mucous membranes and umbilicus, and convulsions may occur.

Diagnosis.—Deep jaundice in a new-born infant, with a large liver and spleen and hæmorrhages without any early evidence of infection, is generally due to this disease.

Prognosis.—Life may last from a few days to as much as 11 months.

Treatment.—No treatment is of any value.

CARCINOMA OF THE BILE-DUCTS

Ætiology.—The incidence of carcinoma of the bile-ducts is about half that of carcinoma of the gall-bladder. It is associated with gall-stones in about 50 per cent. of cases.

Pathology.—The growth arises most frequently in the ampulla of Vater, where a papillomatous projection into the duodenum develops. The common hepatic duct and the common duct are next most affected; a growth of either of the two hepatic ducts is very rare. Primary growths of the cystic duct can rarely be recognised, as at the time of death they are likely to have spread either to the gall-bladder or to the junction with the hepatic duct.

Symptoms.—The first symptom is generally jaundice, which develops gradually and is often intermittent; though the feces are clay-coloured, they generally contain a little stercobilin. Apart from loss of weight and strength the symptoms are those of obstructive jaundice, but pain may be felt in the epigastrium or right hypochondrium, and attacks of colic may occur. In rare cases the symptoms resemble those of duodenal ulcer and there may be no jaundice if ulceration of the growth destroys the sphincter. Occult blood is present in the stools, and the patient may become extremely anæmic. The gall-bladder and less frequently the liver is enlarged. The primary tumour is never palpable. Ascites may occur as a result of secondary malignant peritonitis or of pressure of glands on the portal vein. The course of the disease is sometimes remarkably slow, some cases living for over 2 years after the first attack of jaundice.

The diagnosis from carcinoma of the pancreas, chronic pancreatitis and a stone in the common bile-duct is discussed on p. 705.

Treatment.—Life may be rendered more bearable as well as being considerably prolonged by cholecystenterostomy if the obstruction is in the common bile-duct. In spite of the technical difficulties of the operation it is sometimes possible to excise a growth of the ampulla of Vater, but recurrence is almost invariable.

THOMAS HUNT.

DISEASES OF THE PANCREAS

THE INVESTIGATION OF DISEASES OF THE PANCREAS

The pancreas produces an external secretion—pancreatic juice, and an internal secretion—insulin. The two functions are entirely independent, and in the diseases affecting the former, which are alone considered in this section, glycosuria due to deficient insulin is rarely present.

The pancreatic juice reaches the duodenum by the large pancreatic duct and a small accessory duct. The former runs by the side of the common bile duct for a short distance and then joins it to form the ampulla of the bile-duct, a small cavity in the wall of the descending part of the duodenum, which opens in the biliary papilla, the end of the duct being kept closed by the tonic action of the sphincter of Oddi. In most individuals the pancreatic and common bile-ducts are quite separate, but in some 30 per cent of normal people the two ducts are united terminally and have a common passageway. The accessory pancreatic duct discharges through a small papilla a short distance nearer the pylorus, but in 30 per cent of normal individuals it is not patent or is too small to perform the functions of the main pancreatic duct if the latter is obstructed. The common bile-duct is completely surrounded by the head of the pancreas in 62 per cent of bodies, in the remainder it lies in a more or less deep groove in the gland. It is clear from these anatomical facts that deficient pancreatic digestion may occur owing to failure of the pancreatic juice to reach the intestine either as a result of diffuse disease of the pancreas, which inhibits the activity or actually destroys the secreting cells, or as a result of obstruction caused by a pancreatic or gall stone in, or a growth of, the ampulla of the bile-duct occurring in an individual with an incompetent accessory pancreatic duct. In most cases of chronic inflammation or cancer of the head of the pancreas jaundice will result, but if the accessory duct is incompetent, jaundice accompanied by deficient pancreatic digestion may also be due to obstruction of the ampulla of the bile duct without disease of the pancreas.

The stools in deficient pancreatic digestion—The stools are bulky and pale owing to excess of fat, the proportion of which in the dried faeces may be increased to 60 to 80 per cent from the normal of 15 to 25 per cent. The pallor is still more marked in the presence of jaundice, as stercobilin is then absent or reduced in quantity. The fat is present chiefly in its neutral form, whereas normally only about 10 per cent is unsplitted, in rare cases it separates as oil, which solidifies on cooling. Microscopically oil droplets are seen, together with crystals of fatty acids and soaps, which are formed by bacterial decomposition of the undigested fat, but the proportion of neutral fat to fatty acids and soaps remains high, in contrast with the excess of the latter and small proportion of the former in the fatty diarrhoea of the sprue syndrome (p. 612). Fragments of undigested meat can sometimes be recognised with the naked eye, especially if the presence of excess of fat is prevented by giving a fat free diet. Striated muscle fibres are always recognisable with the microscope, but there is often no excess of undigested starch. In severe diarrhoea associated with rapid passage through the small intestines the stools may contain some excess of undigested fat, meat and starch in the absence of pancreatic disease, conversely the irritating products of bacterial decomposition of undigested fat and meat may themselves give rise to diarrhoea, in which case excess of mucus is often present.

Pancreatic ferments in the duodenal contents, faeces and urine—The duodenum normally contains trypsinogen, which is converted into active trypsin by the coelokinase of the intestinal juice, amyllopsin (diastase) and steapsin (lipase). Under the conditions already described, in which no pancreatic juice reaches the intestine, the ferments cannot be isolated from the duodenal contents obtained through a tube. But it is impossible to recognise with certainty a simple reduction in the quantity present, owing to the great variations which normally occur and the technical difficulties in the quantitative estimation of the ferments. The same is true with regard to their presence in the stools, and only a very rough estimate of the quantity of pancreatic juice secreted can be made by measuring the tryptic activity of the faeces. On the other hand, by giving pure secretin intravenously the pancreatic secretion can be stimulated and readily collected through a duodenal tube, the volume, bicarbonate content and enzyme activity can then be measured. The rate of secretion normally lies between 2 and 5 ml per minute, both the volume and bicarbonate

content are reduced in pancreatic disease, but the enzymes are more difficult to estimate, and being under vagus control their variations in disease are less fully understood. The amounts of lipase and amylase in the blood may readily be determined and are of much value in diagnosis. The former is the more difficult to estimate and in consequence the serum amylase test is more often employed. This ferment is excreted in the urine, though only in small amounts if renal disease is present and the urinary amylase estimation is also of some value in diagnosis. In acute hæmorrhagic pancreatitis the amounts of amylase in the serum are greatly increased. The normal value is defined by units, each of which represents the amount of enzyme which will fully hydrolyse 1 mg. of 2 per cent. starch solution at pH of 7. In acute pancreatitis the serum amylase value may be as high as several thousand units in comparison with normal values of between 100 and 180. This estimation is of great value in the differential diagnosis of the "acute abdomen" as it is almost invariably high in pancreatitis, is never raised in coronary thrombosis and is only very rarely raised in cases of perforated ulcer.

Carbohydrate metabolism.—Although the secretion of insulin is rarely much affected in the diseases of the pancreas considered in this section, a rise in the blood sugar with or without glycosuria is sometimes observed, and the glucose tolerance test may show some deficiency in carbohydrate metabolism. In doubtful cases this is a strong point in favour of pancreatic disease.

In very rare cases an adenoma or carcinoma develops from the cells of the islands of Langerhans and gives rise to hyperinsulinism with symptoms of hypoglycæmia, indistinguishable from those produced by an overdose of insulin; the condition must be considered as one of the possible causes of epileptiform convulsions.

ACUTE NECROSIS OF THE PANCREAS

Synonym.—Acute Hæmorrhagic Pancreatitis.

Ætiology.—The pressure under which bile is secreted is considerably higher than the maximal pressure attained in the pancreatic duct after a meal, when pancreatic secretion is most active. Bile is not, however, forced into the pancreas, as the resistance offered by the sphincter of the common bile-duct is overcome by a smaller pressure. But when the mouth of the common bile-duct is obstructed, the bile may be forced into the pancreatic duct. Normally this may cause no ill effects but if the bile is very concentrated or it is infected, it may activate the pancreatic zymogens: the trypsin causes necrosis with secondary hæmorrhage of the pancreas, and the steapsin causes fat necrosis. If the bile is infected, but not otherwise, suppuration of the pancreas occurs simultaneously.

The obstruction is caused by a gall-stone in 50 per cent. of cases, and in very rare instances by a pancreatic calculus or a round worm. When the lumen is free, the obstruction is probably caused by spasm of the sphincter of the common bile-duct. Necrosis may also follow hæmorrhage caused by a direct injury to the pancreas. It is believed that in some cases acute congestion, œdema and even necrosis of the pancreas may result from intense reflex stimulation of the splanchnic nerves.

Very rarely infection reaches the pancreas by way of the blood-stream in pyæmia and infective endocarditis, and abscesses may result from retrograde thrombosis in suppurative pyelophlebitis. Acute pancreatitis is a rare complication of mumps, but suppuration and necrosis never occur (see p. 174).

Pathology.—Necrosis, hæmorrhages and suppuration are present in varying proportions in the pancreas. Opaque white areas of fat necrosis are found in the fat of the pancreas, the retroperitoneal tissue, omentum and mesentery, and also occasionally in that of more distant parts, such as the pericardium, to which the pancreatic lipase has been conveyed by lymphatics. Bacteria, especially *Bact. coli* and strepto-

cocci, can generally be isolated from the pancreas and often from the gall-bladder. The peritoneal cavity often contains blood-stained fluid, especially in the lesser sac, in the later stages this fluid is infected and suppurative peritonitis may be present.

Symptoms—Without any warning a sudden very violent pain is felt in the epigastrium. It continues without intermission, but paroxysms of still more severe pain occur from time to time. Severe pain across the back is often present. After a short time vomiting begins and is repeated at frequent intervals, the gastric contents are first ejected, and after a time the vomit contains bile. Flatus may be passed, but the bowels are not opened, and no sounds indicating gastro-intestinal activity can be heard on auscultation. The abdomen soon becomes distended, it is very tender on palpation, but the muscles are often not correspondingly rigid. The tenderness and rigidity begin in the epigastrium, but before long become general. In rare cases the enlarged pancreas can be felt, but the rigidity of the abdomen generally makes this impossible. Slight jaundice is occasionally present as a result of pressure of the swollen pancreas on the common bile-duct. The patient soon becomes collapsed with a weak and rapid pulse and slight cyanosis, he appears more severely ill in the first few hours than is generally the case in acute peritonitis. Occasionally he is dyspnoeic. The temperature is not greatly raised and may be subnormal, and leucocytosis is generally absent. The symptoms of vasomotor collapse are due to the absorption of protein-breakdown products which are produced by the proteolytic (tryptic) ferments escaping from the obstructed pancreatic ducts. Glycosuria is rare, possibly because death occurs too rapidly, as the diabetes produced in animals by the removal of the pancreas often does not develop until some days have elapsed.

Diagnosis—The possibility of acute pancreatic necrosis should be considered in all cases of acute symptoms in the upper part of the abdomen in adults, especially if the patient is an elderly obese, alcoholic individual, who has previously suffered from symptoms which might have been due to gall stones or gastro-duodenitis. A carefully taken history may reveal the fact that the patient has previously had one or more similar, but much slighter attacks, probably due to acute but localised necrosis from which complete recovery took place. The symptoms may closely resemble those following perforation of a gastric or duodenal ulcer, but in the latter there is generally a history pointing to the presence of an ulcer before the onset of acute symptoms, vomiting is continuous in pancreatitis, but occurs only at the onset or not at all in perforation, and the hepatic dullness does not alter in pancreatitis, but often disappears owing to the escape of gas through a perforated ulcer, and the abdominal muscles are generally less rigid in pancreatitis than in perforation. In other cases acute intestinal obstruction is simulated, but flatus generally continues to be passed, the abdomen is less distended, and intestinal sounds disappear at once instead of being unusually loud at first. Severe cases with much shock may be confused with coronary infarction. At the operation the discovery of fat necrosis at once makes the diagnosis clear. The serum amylase test is of great value in diagnosis, figures of 200 units per 100 ml of blood or higher being almost pathognomonic of acute pancreatitis, the normal levels lying between 80 and 150.

Prognosis—The most acute cases are usually fatal and the initial shock may even result in sudden death. Some cases run a subacute course, especially if one or more localised abscesses form.

Treatment—The severe shock associated with acute pancreatic necrosis makes immediate operation a procedure of extreme risk. For this reason the first step in treatment must be to correct the fluid and salt balance and the hæmoconcentration which is usually present. Intravenous saline, and plasma should be given at once and if possible the serum chloride and protein estimated. Morphine, complete rest and restriction of all fluids or food by mouth to prevent vomiting must be maintained, and in most cases improvement is rapid. Provided the diagnosis is certain, non-operative treatment on these lines is the safest procedure and operation should only

be considered if signs of increasing peritoneal irritation or the development of jaundice with a rising serum amylase figure make it imperative. At laparotomy any associated gall-bladder disease should be treated, and the abdomen drained, but incision of the pancreas itself is not to be advised unless a localised abscess is found. Permanent deficiency of pancreatic secretion may follow due to a chronic interstitial pancreatitis. The mortality for cases requiring operation lies between 15 and 30 per cent., but the recovery rate in less severe cases treated by intravenous fluids is as high as 90 per cent.

SUBACUTE NECROSIS OF THE PANCREAS

Pathology and Symptoms.—Necrosis may occur in small areas of the pancreas as well as in the generalised form just described. This condition is frequently associated with gall-stones and with penetrating gastric or duodenal ulcer. It gives rise to recurrent attacks of mid- or left-sided epigastric pain, which tends to radiate round the left costal margin or to bore through to the muscles immediately to the left of the lower dorsal spine, when it may simulate renal colic. It may spread upwards to the left shoulder and downwards to the left iliac fossa and even to the left thigh and leg. The attacks generally occur 2 or 3 hours after food, when the functional activity of the pancreas is at its height. The pain may be associated with deep tenderness, but there is little or no rigidity, and the abdomen is often much distended. The patient may be perfectly well in the intervals between attacks. As in acute pancreatic necrosis, the attacks may be associated with cyanosis and a weak, though not specially rapid, pulse. The stools are generally normal, and there is no constant glycosuria, but there may be temporary hyperglycemia and glycosuria during the attacks.

Diagnosis.—Attacks of left-sided pain occurring in cholelithiasis and after cholecystectomy are often caused by subacute pancreatic necrosis, which may also account for pain boring through to the back in gastric and duodenal ulcer, though severe pain of this kind may occur in which the ulcer at operation is found to be free from adhesions and the pancreas healthy. The sudden violent abdominal pain, with tenderness, rigidity and leucocytosis, which may occur in an attack of diabetic coma, is probably of similar origin.

Treatment.—The recurrence of attacks may be prevented if a diet is given which affords as complete rest as possible to the pancreas. The patient should be starved for 3 days and then given carbohydrates alone for 3 days. After that a more liberal diet is allowed, but fats and meat should be given sparingly in spite of the fact that the stools show no evidence of pancreatic insufficiency.

In severe attacks the question of operation requires consideration: gall-stones, if present, should be removed and cholecystectomy performed.

CHRONIC PANCREATITIS

Ætiology and Pathology.—Chronic pancreatitis is generally due to infection spreading up the pancreatic duct. This may be the result of stagnation of pancreatic secretion owing to the presence of a gall-stone in the lower end of the common bile-duct. In rare cases the duct is obstructed by a pancreatic calculus, but this may itself be secondary to infection of the pancreatic ducts. Cancer of the head of the pancreas, and obstruction of the mouth of the common bile-duct by cancer of the ampulla or of the duodenum, are generally complicated by chronic pancreatitis.

When no obvious obstruction is found to account for chronic pancreatitis, the disease may have been due to a gall-stone which has been passed, or infection may have ascended from the duodenum, or descended from the upper biliary passages.

as non calculous cholecystitis is sometimes present. When a chronic gastric or duodenal ulcer erodes the pancreas, the neighbouring part of the gland becomes chronically inflamed.

In chronic pancreatitis the inflammation and secondary fibrosis are mainly interlobular, coarse bands of connective tissue, often visible to the naked eye, separating the lobules of the gland from each other. The head of the pancreas is generally most affected. It is hard and somewhat enlarged.

Symptoms—In chronic pancreatitis the normal functions of the pancreas must be more or less disturbed, but in many cases it is entirely latent, as the inflammation may not be sufficiently severe and widespread to interfere seriously with pancreatic digestion. It is often found accidentally during an operation for gall stones, or at necropsy if the primary disease proves fatal. In an individual in whom the pancreas completely surrounds the common bile duct, jaundice is likely to develop. It may be the only symptom, and chronic painless obstructive jaundice, developing insidiously may be due to chronic pancreatitis as well as to carcinoma. The gall bladder is dilated, but it is generally difficult to recognise by palpation, and the liver is often enlarged and abnormally hard, but not tender. In cases in which pancreatic deficiency occurs, the stools contain excess of fat and undigested meat (p. 701) and diarrhoea may result, the deficient digestion causes emaciation with increasing weakness, steatorrhoea may be severe with much diarrhoea, extreme emaciation and anorexia.

Diabetes rarely results from chronic pancreatitis, but it may occur in very chronic cases if the inflammation invades the islands of Langerhans.

Chronic pancreatitis may be painless, but in the majority of cases periodic attacks of pain occur, lasting from 1 to 5 days and recurring every few weeks or months—chronic relapsing pancreatitis. The pain is often severe and tends to radiate along the left costal margin and to bore through to the muscles immediately to the left of the lower dorsal spine and to the angle of the scapula. The pain is often worse lying down than sitting up and usually requires morphine for its relief. Left sided pain of this kind in gall bladder disease should suggest the possibility that the pancreas is involved, and in chronic gastric and duodenal ulcer that penetration into the pancreas has occurred.

Diagnosis—It is rarely possible to determine with certainty whether chronic pancreatitis is present as a complication of gall stones or of the other conditions with which it may be associated. If hyperglycæmia with or without glycosuria develops in such a case, it is extremely probable that the pancreas is becoming affected. The changes in the faeces, which result from the absence of pancreatic digestion, do not prove that the pancreas is affected in a case of chronic jaundice, as obstruction of the ampulla of the bile duct may prevent the pancreatic juice as well as the bile from reaching the duodenum although the pancreas is healthy.

The possibility of chronic pancreatitis should be considered in all cases of chronic jaundice in which the cause is doubtful. Attacks of pain, even in the absence of a characteristic history, makes the presence of gall stones probable. In the absence of such attacks especially if the gall bladder be enlarged, either chronic pancreatitis or a growth is probably present. A growth is much more commonly associated with chronic pain, and emaciation and weakness develop more relentlessly than with chronic pancreatitis. It is often impossible, however, even at an operation, to distinguish between a growth of the head of the pancreas and chronic pancreatitis. Only when a patient recovers completely and permanently is it possible to be certain that the condition was inflammatory. The periodic attacks of chronic relapsing pancreatitis are often mistaken for those of duodenal ulcer, but there is less vomiting and loss of weight in ulcer and the pain during attacks is more continuous in pancreatitis. In some cases the pain of pancreatitis may simulate a coronary infarction and diverticulitis of the colon may also have to be considered in the differential diagnosis.

Prognosis—The prognosis depends upon that of the primary condition in

secondary cases and the presence of chronic pancreatitis does not alter the outlook in operations for gall stones. In cases of apparently primary pancreatitis recovery has taken place after an exploratory operation in which nothing was done. Chronic pancreatitis causes death only in the presence of complications. Morphine addiction is not uncommon, and the continued attacks of pain and loss of weight may lead to serious secondary neurosis.

Treatment—It is only necessary to consider the treatment of those cases which appear to be primary as when the pancreatitis is secondary no treatment beyond what is necessary for the primary disease is required. If the jaundice does not abate within 3 months or a shorter period if the patient rapidly loses weight and strength or tests show that the functional efficiency of the liver is becoming impaired an operation should be performed. A cholecystenterostomy will cure the jaundice remove one source of irritation of the pancreas by draining the infected bile and prevent the development of secondary infection and necrosis in the liver. In chronic cases without jaundice the diet should be kept low in fats alcohol avoided and full doses of pancreatin given after each meal. Hexamethonium salts are sometimes effective in relieving pain probably by their action in depressing vagal action and so reducing pancreatic secretion. Various forms of surgical treatment have been suggested including division of the sphincter of Oddi thoracolumbar sympathectomy and even excision of the pancreas, but results have been uncertain.

FIBROSIS OF THE PANCREAS IN INFANTS

Synonym—Fibrocystic Disease of the Pancreas

Ætiology and Pathology—This disease was first described in 1905 but it was not until 1938 that it was fully recognised as a clinical and pathological entity. It is frequently familial and is by no means so rare as was believed being found in between 1 and 2 per cent of routine admissions to children's wards and in approximately 3 per cent of all necropsies in infants. The main changes are found in the pancreas, lungs and intestine. In the pancreas the acini and small ducts are blocked by inspissated eosinophilic secretion with resulting atrophy of the acini and gradual replacement by fibrous tissue. The islands of Langerhans are not affected. Similar changes to those occurring in the pancreas are found in the lungs and intestine and it is probable that the condition is a generalised disease of mucus secreting glands throughout the body due to some nutritional deficiency. Broncho pneumonia is almost always present with bronchiectasis, fibrosis and abscesses of the lungs except in infants dying in the very early neonatal period.

Symptoms—Symptoms generally appear soon after birth. Extreme emaciation occurs in spite of a very good appetite owing to the absence of all pancreatic ferments from the intestines. The abdomen is distended. Diarrhoea is common and the stools are often large, pale and offensive but much of the fat is split owing to bacterial action in the colon. A chronic cough is present from an early age and signs of pulmonary infection appear. Clubbed fingers and cyanosis with purulent offensive sputum usually develop later and dominate the clinical picture.

Diagnosis—The disease should be suspected in all cases of chronic respiratory infection and nutritional deficiency in children. A clinical diagnosis is often possible from an accurate history and examination alone but may be confirmed by the finding of a high fat content in the stools together with an absence of pancreatic ferments in the duodenal juice. If death occurs in the first few months of life the condition is rarely distinguished from many disorders causing chronic wasting with terminal broncho pneumonia but if the illness lasts longer celiac disease is simulated. In this case the pulmonary symptoms should arouse suspicion of fibrocystic disease.

Treatment—The results of treatment are disappointing. The diet should be

low in fats but high in carbohydrates, proteins and vitamins. Protein hydrolysates are a valuable addition to the feeds, if they can be tolerated and full doses of pancreatin, 1 to 2 g. per meal, should also be given.

Therapy with antibiotics usually fails to control the pulmonary infection completely, but should be given a full trial. Death from broncho-pneumonia is the rule, but the prognosis, though bad, is not quite hopeless, and a few patients survive for a number of years or even exceptionally appear to make a full recovery.

SYPHILIS OF THE PANCREAS

The pancreas is affected in 20 per cent. of cases of congenital syphilis in the newborn; in most cases the liver is simultaneously affected, and somewhat less frequently the spleen, bones, lungs and other organs. The gland is enlarged and hard owing to proliferation of the interlobular connective tissue; the gland-cells atrophy, but the islands of Langerhans escape. Acquired syphilis occasionally gives rise to gummata of the pancreas.

Symptoms.—The symptoms are those of chronic pancreatitis or carcinoma of the pancreas. The tumour may be palpable, and it may lead to obstruction at the pylorus or duodeno-jejunal flexure with persistent vomiting. The occurrence of diabetes in a syphilitic patient should suggest that the pancreas may be affected. The Wassermann reaction should always be tested in cases of suspected chronic pancreatitis and carcinoma of the pancreas, whether the diagnosis is made clinically or at an operation, and in diabetes, and anti-syphilitic treatment instituted if it is positive.

PANCREATIC CALCULI

Pathology.—Diffuse calcification in the parenchyma of the pancreas is found by radiography in about 10 per cent. of cases of chronic pancreatitis, but true pancreatic calculi occurring in the ducts themselves are rare. When present they may be single or as many as two or three hundred. They are white, yellow or brown, and vary in size from mere sand to smooth or irregularly shaped masses, an inch or more in length. They consist of tribasic calcium phosphate or of an amorphous debris mixed with calcium carbonate. Even though pancreatic juice normally contains no calcium carbonate, this is the chief constituent of the calculi, which consequently, on radiographic examination, throw much more definite shadows than gall-stones. Calculi never form in a healthy pancreas; they result from infection of the ducts and stagnation of the secretion. The ducts behind the calculi are dilated, and chronic pancreatitis is present, but suppuration is very rare. The condition may be associated with gall-stones.

Symptoms and Treatment.—In 30 or 40 per cent. of cases calculi are completely "silent" but when they cause symptoms they are those of the associated chronic pancreatitis; the attacks of pain begin and end more abruptly if a stone is present. If the presence of definite calculi can be proved in contrast to the irregular calcification of chronic inflammation, surgical exploration is justified when it may be possible to remove one or more stones even though others may still remain.

PANCREATIC CYSTS

Ætiology and Pathology.—Simple obstruction of the pancreatic duct leads to atrophy of the secreting tubules and not to the formation of cysts. When chronic

secondary cases, and the presence of chronic pancreatitis does not alter the outlook in operations for gall stones. In cases of apparently primary pancreatitis recovery has taken place after an exploratory operation in which nothing was done. Chronic pancreatitis causes death only in the presence of complications. Morphine addiction is not uncommon, and the continued attacks of pain and loss of weight may lead to serious secondary neurosis.

Treatment.—It is only necessary to consider the treatment of those cases which appear to be primary, as when the pancreatitis is secondary no treatment beyond what is necessary for the primary disease is required. If the jaundice does not abate within 3 months, or a shorter period if the patient rapidly loses weight and strength or tests show that the functional efficiency of the liver is becoming impaired, an operation should be performed. A cholecystenterostomy will cure the jaundice, remove one source of irritation of the pancreas by draining the infected bile, and prevent the development of secondary infection and necrosis in the liver. In chronic cases without jaundice the diet should be kept low in fats, alcohol avoided and full doses of pancreatin given after each meal. Hexamethonium salts are sometimes effective in relieving pain, probably by their action in depressing vagal action and so reducing pancreatic secretion. Various forms of surgical treatment have been suggested, including division of the sphincter of Oddi, thoracolumbar sympathectomy and excision of the pancreas, but results have been uncertain.

FIBROSIS OF THE PANCREAS IN INFANTS

Synonym.—Fibrocystic Disease of the Pancreas

Ætiology and Pathology.—This disease was first described in 1905, but it was not until 1938 that it was fully recognised as a clinical and pathological entity. It is frequently familial and is by no means so rare as was believed, being found in between 1 and 2 per cent of routine admissions to children's wards and in approximately 3 per cent of all necropsies in infants. The main changes are found in the pancreas, lungs and intestine. In the pancreas the acini and small ducts are blocked by inspissated eosinophilic secretion with resulting atrophy of the acini and gradual replacement by fibrous tissue. The islands of Langerhans are not affected. Similar changes to those occurring in the pancreas are found in the lungs and intestine, and it is probable that the condition is a generalised disease of mucus secreting glands throughout the body, due to some nutritional deficiency. Broncho pneumonia is almost always present, with bronchiectasis, fibrosis and abscesses of the lungs, except in infants dying in the very early neonatal period.

Symptoms.—Symptoms generally appear soon after birth. Extreme emaciation occurs in spite of a very good appetite owing to the absence of all pancreatic ferments from the intestines. The abdomen is distended. Diarrhoea is common and the stools are often large, pale and offensive, but much of the fat is split owing to bacterial action in the colon. A chronic cough is present from an early age and signs of pulmonary infection appear. Clubbed fingers and cyanosis with purulent offensive sputum usually develop later and dominate the clinical picture.

Diagnosis.—The disease should be suspected in all cases of chronic respiratory infection and nutritional deficiency in children, a clinical diagnosis is often possible from an accurate history and examination alone, but may be confirmed by the finding of a high fat content in the stools, together with an absence of pancreatic ferments in the duodenal juice. Treatment.—The results of treatment are disappointing. The diet should be

low in fats but high in carbohydrates, proteins and vitamins. Protein hydrolysates are a valuable addition to the feeds, if they can be tolerated and full doses of pancreatin, 1 to 2 g. per meal, should also be given.

Therapy with antibiotics usually fails to control the pulmonary infection completely, but should be given a full trial. Death from broncho-pneumonia is the rule, but the prognosis, though bad, is not quite hopeless, and a few patients survive for a number of years or even exceptionally appear to make a full recovery.

SYPHILIS OF THE PANCREAS

The pancreas is affected in 20 per cent. of cases of congenital syphilis in the newborn; in most cases the liver is simultaneously affected, and somewhat less frequently the spleen, bones, lungs and other organs. The gland is enlarged and hard owing to proliferation of the interlobular connective tissue; the gland-cells atrophy, but the islands of Langerhans escape. Acquired syphilis occasionally gives rise to gummata of the pancreas.

Symptoms.—The symptoms are those of chronic pancreatitis or carcinoma of the pancreas. The tumour may be palpable, and it may lead to obstruction at the pylorus or duodeno-jejunal flexure with persistent vomiting. The occurrence of diabetes in a syphilitic patient should suggest that the pancreas may be affected. The Wassermann reaction should always be tested in cases of suspected chronic pancreatitis and carcinoma of the pancreas, whether the diagnosis is made clinically or at an operation, and in diabetes, and anti-syphilitic treatment instituted if it is positive.

PANCREATIC CALCULI

Pathology.—Diffuse calcification in the parenchyma of the pancreas is found by radiography in about 10 per cent. of cases of chronic pancreatitis, but true pancreatic calculi occurring in the ducts themselves are rare. When present they may be single or as many as two or three hundred. They are white, yellow or brown, and vary in size from mere sand to smooth or irregularly shaped masses, an inch or more in length. They consist of tribasic calcium phosphate or of an amorphous debris mixed with calcium carbonate. Even though pancreatic juice normally contains no calcium carbonate, this is the chief constituent of the calculi, which consequently, on radiographic examination, throw much more definite shadows than gall-stones. Calculi never form in a healthy pancreas; they result from infection of the ducts and stagnation of the secretion. The ducts behind the calculi are dilated, and chronic pancreatitis is present, but suppuration is very rare. The condition may be associated with gall-stones.

Symptoms and Treatment.—In 30 or 40 per cent. of cases calculi are completely "silent" but when they cause symptoms they are those of the associated chronic pancreatitis; the attacks of pain begin and end more abruptly if a stone is present. If the presence of definite calculi can be proved in contrast to the irregular calcification of chronic inflammation, surgical exploration is justified when it may be possible to remove one or more stones even though others may still remain.

PANCREATIC CYSTS

Ætiology and Pathology.—Simple obstruction of the pancreatic duct leads to atrophy of the secreting tubules and not to the formation of cysts. When chronic

pancreatitis is also present retention cysts may develop Hydatid cysts may occur in the pancreas, and congenital cystic disease, generally associated with cystic disease of the kidneys, may occur

Single large pancreatic cysts the origin of which is unknown, may contain as much as 14 pints of fluid Multiple cysts of various sizes, often quite small, may occur in the absence of pancreatitis The contents are generally turbid and dark reddish brown or yellow The fluid is alkaline, slightly viscid and albuminous and may contain altered blood Microscopically degenerated epithelial cells, leucocytes and occasionally crystals of cholesterol and rarely of leucin and tyrosin are found The pancreatic ferments are often absent, especially in old cysts

A large proportion of so called pancreatic cysts are really collections of fluid in the lesser sac of the peritoneum, the foramen of Winslow having been occluded by peritonitis About a quarter follow an injury to the pancreas, which causes the escape of blood and pancreatic juice into the lesser sac with secondary peritonitis In the remaining cases serous fluid collects slowly as a result of local peritonitis secondary to pancreatitis, the condition being analogous to a pleural effusion following pneumonia.

Symptoms—The tumour is generally discovered by chance before the development of any symptoms Sometimes attacks of epigastric pain, which may radiate to the left shoulder, occur, they are sometimes accompanied by vomiting wasting and jaundice Diabetes rarely develops

The tumour is generally in the centre of the upper part of the abdomen, but it often extends farther to the left than the right It does not move on deep respiration and is only very slightly movable in any direction As it grows it extends farther down and may finally appear to fill the entire abdomen It is smooth, rounded and elastic, a thrill is often produced on striking it.

Its relation to the stomach and colon can be readily determined by means of radiography after a barium meal and enema It is first behind the stomach, but as it enlarges it generally reaches the anterior abdominal wall between the stomach above and the transverse colon below Less frequently it comes forward above the stomach or below the transverse colon between the leaves of the mesocolon. It generally grows very slowly, but sudden enlargement may result from hæmorrhage into it.

Diagnosis—There should be no difficulty in diagnosing a pancreatic cyst from ascites and from a hydronephrosis, enlarged gall bladder, ovarian cyst or distended bladder It is impossible to distinguish a true pancreatic cyst from a pseudo-pancreatic cyst clinically, even at an operation the distinction may be impossible Mesenteric cysts are generally more movable than pancreatic cysts

Treatment—The cyst should be emptied and drained by operation No attempt should be made to remove it because of the dense adhesions which often fix it to its surroundings The immediate results of operation are very satisfactory, but a recurrence is not uncommon

creatic calculus Secondary deposits are often found in the neighbouring lymphatic glands, the liver and peritoneum, and less often in more distant organs

Symptoms—When the head of the pancreas is involved, jaundice is generally present owing to pressure on the common bile duct, but the latter may escape if it is not embedded in the gland The jaundice increases until it is very intense, bile being then completely absent from the faeces The gall bladder is almost always distended and is generally palpable; the liver is also generally large and hard When the growth is confined to the body or tail of the pancreas there is no jaundice unless the duct is compressed by a secondary deposit, and neither the gall bladder nor liver is enlarged Pain is present in 80 per cent of cases, in 65 per cent it is the first symptom The patient complains of a dull, gnawing, aching pain deeply situated in the upper abdomen and extending to the back It is constantly present, and unrelated to meals or bowel actions In some cases it is paroxysmal It is generally bilateral, but occasionally confined to the left, especially with growths of the tail, and tends to be worst at night The pain may simulate that produced by a spinal tumour, when it is probably caused by involvement of the celiac plexus Wasting is rapid in almost all cases, and the patient becomes progressively weaker If the head of the pancreas is involved, the stools may have the characteristics described on page 701, and diarrhoea is likely to occur, but typical fatty stools are passed in only a small minority of cases Glycosuria is only occasionally present but impaired glucose tolerance is more frequently found A growth of the body or tail does not interfere with digestion, but loss of appetite is very characteristic

A tumour of the head of the pancreas is not often palpable, as it is deep seated and likely to be hidden by the enlarged liver and the ascites, which often develops as a result of malignant peritonitis or pressure on the portal vein A tumour of the body or tail of the pancreas is more frequently palpable, especially shortly before death when emaciation is extreme It forms a hard, fixed mass extending across the abdomen on a level with the umbilicus, especially to the left, and is generally not tender A pancreatic tumour can sometimes be seen as an indefinite shadow by radiography in the lateral position, and with a barium meal the duodenum may appear as a thin distended arc due to pressure from the enlarged head of the pancreas

Insomnia, depression, anxiety and restlessness may be so prominent and so out of proportion to the abdominal pain, which may for a time be absent that a neurosis may at first be diagnosed

Diagnosis—Chronic jaundice due to carcinoma of the head of the pancreas must be diagnosed from chronic pancreatitis, subacute hepatitis and cirrhosis of the liver, a gall stone in the ampulla of the bile duct and carcinoma of the ampulla In carcinoma pain is more continuous and the loss of appetite greater than in chronic pancreatitis and the general deterioration in health is more steady Liver function tests are usually abnormal in chronic hepatitis A gall stone rarely reaches the ampulla and causes jaundice without a preceding attack of colic, whereas jaundice is often the first symptom in carcinoma of the head of the pancreas, the jaundice in the former is often incomplete and intermittent instead of complete and permanent, pyrexia is common, and rigors may occur owing to infection of the bile passages In carcinoma of the ampulla the jaundice which is accompanied as in carcinoma of the pancreas by dilatation of the gall bladder, is less complete and more intermittent than might be expected, it can sometimes be recognised with the radiograph by the characteristic filling defect it produces in the duodenum, and it always leads to the presence of occult blood in the stools

The possibility of a growth of the tail of the pancreas should be considered in a patient without jaundice whose general condition suggests that he is suffering from cancer, but in whom no evidence of disease can be found in the organs most commonly affected The possibility is converted to a probability if he complains of severe pain boring through to the left side of the back or a fixed tumour becomes palpable A

normal diastase index and stools showing no deficiency in fat or meat digestion do not militate against the diagnosis.

Prognosis.—Death generally occurs within 6 months of the onset of symptoms and is rarely delayed beyond a year.

Treatment.—A cholecystenterostomy should be performed in all cases of obstructive jaundice in which a growth of the pancreas is the probable cause. By relieving the jaundice, any itching already present is overcome and the almost intolerable itching which is likely to develop at a later stage is prevented. Moreover, pain and diarrhoea may become less severe and the progress of the disease appears to be delayed, some patients remaining free from symptoms and regarding themselves as completely cured for 6 to 18 months after cholecystenterostomy performed for the relief of jaundice. Moreover, in other cases permanent recovery may follow the operation when performed for a supposed growth of the pancreas, the surgeon having mistaken chronic pancreatitis for a growth. In rare instances a localised growth of the pancreas has been successfully removed. Total pancreatectomy has been successfully performed in many cases and a number of 5-year cures are reported. The mortality of the operation is high and, if successful, a maintenance dose of insulin of about 40 units a day is permanently required, with very large doses of pancreatic extracts after food.

VISCEROPTOSIS

The position of the viscera in the abdomen varies widely in different individuals and extreme variations are compatible with perfect health and normal digestion. In many normal subjects the stomach, colon or other organs are found to lie low in the abdomen, but this is no indication that they have "dropped" to this position, and such terms as gastropptosis or colopptosis should, therefore, not be employed. Even when any true ptosis develops, as after pregnancy or following severe loss of weight, it is doubtful if it causes any significant symptoms or interference with function. Many patients who in the past were thought to suffer from visceroptosis were, in fact, overweight and the post-prandial discomfort of which they complained was due to a heavy pendulous abdomen and to over-eating. There is no good evidence that a colon lying low in the pelvis is ever for this reason a cause of constipation or presents any special danger of kinking or obstruction, and there is no place for surgery in fixing or altering the position of any of the digestive organs, as a therapeutic measure; it is indeed doubtful whether the term visceroptosis should not now be given up altogether and it is only in the case of the kidney that ptosis is a matter of importance when it can be shown to give rise to Dietl's crises (*q v.*). Undue mobility of one or other part of the colon particularly the sigmoid due to a long mesentery, may be a factor in the causation of volvulus but this is in no way due to abnormal ptosis of the organ.

GASTRO-INTESTINAL ALLERGY

When short, recurrent attacks of abdominal pain, vomiting and diarrhoea, either separately or in any combination, are not obviously the result of food poisoning, intestinal obstruction, or biliary or renal colic, the possibility of abdominal allergy should be considered. The onset is sudden, and the attacks terminate abruptly after a period lasting for a few minutes to 24 or 48 hours. The pain may occur in any part of the abdomen, but especially in the centre, and its situation may vary in different attacks. It may be extremely severe and only partly relieved by morphine. It is often associated with vomiting and diarrhoea, or either, especially diarrhoea, may occur alone. The diarrhoea generally consists of the passage of a single watery stool, which may contain mucus, in which are occasionally found many eosinophil cells and less frequently red blood corpuscles. The stools passed before and after

such a watery stool are generally quite normal. The patient has no abdominal symptoms of any kind in the intervals between the attacks, which may occur almost every day or not more than once or twice a year. Nothing abnormal is found on examining the abdomen between the attacks, and during the attacks there is little or no rigidity and generally little or no tenderness. Erythematous or urticarial rashes may sometimes occur, either during or after attacks.

The patient often gives a family history of asthma, hay fever, eczema, urticaria or migraine, and he is often himself a sufferer from one or other of these conditions. In some cases the vomiting or diarrhoea is often or always preceded by rhinorrhoea. The abdominal attacks generally occur, however, during periods of complete freedom from other allergic manifestations, so that the frequent presence of slight eosinophilia is an important help in diagnosis. Still more characteristic is the complete relief obtained by injecting 5 to 10 minims of adrenaline (1 in 1,000), as this drug has no effect on any other form of abdominal pain.

Cutaneous reactions may show that the patient is sensitive to certain articles of food, especially wheat, milk and eggs in the case of children, and pork or other pig food, cabbage, potatoes and chocolate in adults, but the absence of such reactions does not exclude an allergic origin of the symptoms, nor does their presence prove with certainty that the articles consumed must be excluded from the diet. Sensitiveness to foods frequently consumed is rarely recognised by the patient, who is, however, generally aware of an idiosyncrasy to such articles of diet as strawberries, tomatoes, onions, spinach, cucumber, melon, shell fish and turtle. Gastro intestinal allergy occurs at all ages, but is most common in infants and children. In rare cases attacks are brought on by foreign proteins absorbed by the nasal mucous membrane.

Abdominal migraine—In some cases of migraine the headache appears to be entirely replaced by abdominal pain and in others by a persistent migrainous dyspepsia which resembles chronic cholecystitis but is not due to any organic disease of gall-bladder or liver.

Treatment—The patient should avoid any articles of food which he has found give rise to attacks, and also any which give a strongly positive cutaneous reaction. As in asthma, this rule must be applied with great caution in the case of wheat, milk and eggs in children, as the malnutrition following deprivation from these foods may more than outweigh the questionable improvement which may occur in the allergic attacks. If attacks continue to be frequent, the effect of ephedrine hydrochloride, gr. 1 three times a day before meals should be tried. Nocturnal or early morning attacks may be prevented by taking gr. 1 to 2 of phenobarbitone at night with an additional dose of ephedrine. The patient should learn to give himself adrenaline, and at the first sign of an attack he should inject the smallest dose which experience shows prevents an attack; generally 3 to 5 minims are sufficient. The injection can be repeated at intervals if the attack does not at once completely disappear.

Various elimination diets may be tried in the detection of food sensitisation, but are difficult to carry out efficiently and for this reason often give unsatisfactory results.

THOMAS HUNT

DISEASES OF THE PERITONEUM

ACUTE PERITONITIS

Definition—Peritonitis results from infection of the peritoneum with bacteria. When it is dubbed acute, the acuteness refers usually to a condition which becomes severe in a short space of time, commonly a matter of several hours. Because of the large area of the peritoneum and its great powers of absorption the results may be grave, because of its intimate relationship to the alimentary canal and to viscera,

the risks of such infection are high. The inflamed peritoneum loses its lustre from œdema and produces both a serous and fibrinous exudate.

Ætiology—Infection may reach the peritoneum (1) from without (2) by the blood stream and (3) from the contained organs.

1 Infection from without is possible in the case of wounds but is of infrequent occurrence. Severe abdominal wounds commonly implicate the contained viscera and the consequent peritonitis is usually the result of this.

2 Infection by the blood stream is an occasional though uncommon mode of infection. In streptococcal and staphylococcal septicæmia peritonitis may occur as a terminal event. It frequently gives rise to so few symptoms however, that its existence is unrecognised during life. When pneumococcal peritonitis complicates pneumococcal lesions elsewhere the infection is undoubtedly blood borne.

3 Infection from contained or neighbouring organs is by far the commonest cause of peritonitis. The majority of cases depend more or less directly on the passage of bacteria from within the alimentary canal owing to changes in its walls. The appendix is the most frequent seat of the primary condition. Where there is no actual breach of continuity in the organ bacteria escaping through its damaged walls are generally contained by a local plastic reaction in which omentum and neighbouring bowel viscera and parietal peritoneum, singly or together adhere to the inflamed organ and to one another through a fibrinous exudate. This protective structure usually resolves completely if the infection spontaneously subsides. Where the infection is more severe a localised abscess forms inside it. When however the infection is particularly virulent or the patient's resistance unusually poor a sufficient local reaction does not take place and spreading diffuse peritonitis results. This is commonest in children and in the old. It may be brought about, even when the local reaction has been good by unskilful operative interference. Diverticulitis and acute cholecystitis are occasional causes of this type of acute peritonitis but are more commonly restricted by local adhesive changes. Peritonitis complicating typhoid fever in the absence of perforation and pneumococcal peritonitis when associated with pneumococcal enteritis have a similar origin.

In intestinal obstruction and strangulated hernia the changes which occur in the bowel wall speedily permit the passage of organisms through it to the peritoneum. The organisms present are usually *Bact. coli* with streptococci and staphylococci.

Perforation of a hollow viscus into the peritoneal cavity is responsible for some of the most virulent and widespread cases of peritonitis. The lower the perforation in the bowel the more virulent will the resulting infection be. The appendix is the commonest source of gangrene or a perforating ulcer leading to a sudden peritoneal infection before any gradual passage of organisms has had time to produce a local peritoneal reaction. Perforating ulcers of the stomach and duodenum come next in order of frequency. Less common causes are perforating ulcers of the ileum the most important of which is the typhoid ulcer, rupture of the gall bladder or bile ducts and perforating wounds of any of the hollow organs or leakage from surgical anastomoses. Abscesses of the liver appendix gall bladder or Fallopian tubes occasionally burst into the general peritoneal cavity. Infection of the peritoneum may also result by direct spread from neighbouring parts. This type is particularly common in women spread taking place either directly through the Fallopian tubes or by lymphatic permeation of the uterine walls. Peritonitis is a very rare sequel to infections of the lung and pleura although the reverse is far from unusual. In the infant an infection of the thrombosed umbilical vein may lead to peritonitis by direct spread.

Symptoms.—As acute peritonitis is almost invariably a secondary condition its symptoms and course are subject to very considerable variations, depending not only on the nature of the primary lesion from which it arises and on the nature and virulence of the infecting organism but also on the general condition of the patient.

1 *Acute fulminant generalised peritonitis*—This is usually associated with the

perforation of a hollow organ or the sudden bursting of an abscess into the peritoneum, and owes its chief characters to the sudden flooding of the peritoneal cavity with infective material. The patient may have been free from any symptoms of ill health and is suddenly seized with acute abdominal pain, accompanied sometimes by a sensation of something having given way. The pain may at first be localised in position and thus help in the diagnosis of the actual lesion but it speedily spreads to the whole abdomen and is followed almost at once by a feeling of syncope or collapse. Within a few minutes the patient becomes cold and pale, his features are pinched and betray the most intense anxiety, beads of sweat stand out upon the skin, and the pulse may be almost imperceptible. He complains of nausea, but does not often vomit, and his respirations are shallow and quickened. In a short time some improvement takes place, the pulse though rapid, is of better volume, and the pain may take on an intermittent colicky character. The abdomen is absolutely rigid and is usually retracted, it is very tender on pressure. The liver dullness is usually absent, but this is only important if an abdominal examination made at the onset of the attack revealed a normal area of dullness. These symptoms may be sufficiently severe to lead to death by themselves, more usually they gradually merge into the symptoms of the consequent acute peritonitis itself. The latter are reactive in nature and are due to nature's attempts to limit the process.

If not relieved by operation at an early stage, the patient's condition usually worsens rapidly. He becomes anxious and restless. Vomiting is now frequent and, due to this and to other loss of fluid by sweating and exudation into the peritoneal cavity, the subcutaneous tissues become shrunk and give the patient the so called "facies Hippocratica." The tongue is dry and furred and the teeth become covered with sordes. The pulse increases in rate and becomes thready and later running in character, and the temperature, which at first may be subnormal, rises. The abdomen presents a uniformly board like rigidity and is extremely tender. It is held immovable, respiration being entirely thoracic and the patient lies with his knees drawn up to relieve the abdominal tension. There is usually absolute constipation and the intestinal sounds are absent. Gradually the paralytic intestine becomes dilated and the abdomen distended. Vomiting becomes more frequent. The vomited matter is usually only small in quantity, it speedily becomes exceedingly foul though it is rarely faecal, and the breath is extremely offensive. The urine is scanty and may contain traces of albumin and its passage may produce a paroxysm of pain.

The pulse rate rises still more, the restlessness increases, the features become more pinched, the limbs become cold from peripheral circulatory failure, the skin takes on a cyanotic hue and the patient dies, his consciousness usually unimpaired until near the end.

Such is the picture, rarely seen nowadays of fulminant general peritonitis, with death occurring in from 24 to 48 hours. Its outstanding features are those of profound shock and toxæmia measures of the high grade of peritoneal absorption. In the aged, and in patients with Bright's disease, the symptoms may be atypical, pain may be but little marked and vomiting and tenderness may be absent, while the bowels may act freely throughout. The great restlessness the condition of the tongue, the pulse and the ultimate meteorism will however, usually indicate the true nature of the condition.

2. *Acute spreading peritonitis*—In this variety there is no sudden flooding of the peritoneal cavity with infective material. Instead there is a gradual but usually quite rapid spread of the infection from some focus which has not been limited by the protective screen referred to above. It accompanies many cases of appendicitis and is a sequel of intestinal obstruction if unrelieved for a sufficiently long period. The peritoneal reaction is intense, and the coils of intestine become glued together with a sticky exudate, while pockets of pus form between them. The pain is at first localised to the region of origin but as the infection spreads it extends until it

may become generalised over the whole abdomen. It is, however, never so intense as in the preceding variety, and may be distinctly spasmodic in character. The general abdominal symptoms are also less severe, the tenderness, rigidity, meteorism and constipation being of varying grade. The aspect of the patient betokens a profound septic infection, the tongue is furred and dry, the pulse rapid and the temperature of the hectic type. Rigors and sweats are not uncommon, and if left alone the case may terminate with fatal septicæmia or suppurative pyelophlebitis; in rare cases the pus may accumulate and burst either externally in the region of the umbilicus or into one of the hollow viscera. Sometimes the condition subsides to be followed by the swinging temperature suggestive of a localised collection of pus. Such collections are most common in the subphrenic spaces and in the pelvis.

3. *Acute localised peritonitis*.—Here the infection has been prevented from spreading far from such a focus as, for example, the appendix or gall-bladder, by a plastic adhesion of adjacent structures. The initial symptoms are those of the causal condition, e.g. acute appendicitis, acute cholecystitis. The features of the circumscribed peritonitis are those of rigidity of the adjacent abdominal wall and tenderness on deep pressure. All the structures concerned in the walling-off process swell with œdema, and a mass, of greater or lesser size, forms. This may be palpable from about the third or fourth day after the onset. Thereafter it either slowly disappears in the course of a week or so, during which time it becomes less tender, or it gradually enlarges to form an acute abscess, characterised by the tender mass and accompanied by fever and leucocytosis.

4. *Pneumococcal peritonitis*.—This presents certain fairly characteristic features, which in many cases enable the nature of the infection to be correctly diagnosed from the clinical picture alone. It is far more frequent in children than in adults, and in girls than boys in the proportion of nearly 7 to 3. It occurs in a diffuse and in an encysted form, depending probably on the resistance of the patient. In many cases there exists a definite pneumococcal enteritis, the organisms penetrating the wall of the bowel and so infecting the peritoneum. The predominance of the disease in girls is probably due to the female genitals being a source of infection, as the pneumococcus has been cultivated from the vagina in some instances. In the majority however, the peritonitis is part of a pneumococcal septicæmia; thus, when it is secondary to pneumococcal disease of the middle ear, local pneumococcal abscesses or pneumococcal arthritis, the blood-stream appears to be the route of infection, and it probably is so also in those cases which follow pneumonia or empyema.

There is a striking resemblance between the symptoms of most forms of pneumococcal infection, a resemblance which strongly supports the view of their origin in a septicæmia. The onset is usually sudden, often accompanied by a chill and a high temperature, the pain is violent and persistent, and the prostration severe. The patient has the characteristic flush, the respiratory rate is raised and the accessory muscles of respiration are called into play. Vomiting is frequent, and tenderness and rigidity are marked; but in place of the usual absolute constipation there is frequently profuse diarrhœa, which, associated with the other symptoms of acute peritonitis, is often almost diagnostic. In the diffuse form, unless operation is undertaken, death takes place early; but if the patient lives long enough there may be a sudden fall of temperature about the seventh day, as in pneumococcal pneumonia.

The encysted and more common variety of pneumococcal peritonitis is less severe and shows a remarkable tendency for pus to collect in the lower abdomen. There is the same acute onset as in the diffuse variety but the patient then appears to improve for a few days. Later, however, he gets gradually worse, the abdomen becomes distended, the diarrhœa changes to obstinate constipation and an abscess forms in the lower abdomen and finally, if unrelieved, bursts at the umbilicus. The exudate in these cases is a greenish, odourless pus, which is sufficiently characteristic to enable the infection to be diagnosed when it is discovered at operation.

5 *Gonococcal peritonitis*—Gonococcal peritonitis is rare, it occurs both as an acute diffuse affection of the peritoneum and as a localised pelvic inflammation. It is commoner in females than in males, owing to the ready channel for infection through the Fallopian tubes, and when it occurs in males it is usually secondary to epididymitis. The infection is generally a mixed one, the more fragile gonococcus being readily overgrown, and some cases of unexplained peritonitis, which on culture show only *Bact. coli*, are possibly gonococcal in origin. The symptoms do not differ in the diffuse cases from those of other forms of acute peritonitis, although the primary focus usually gives rise to symptoms. The prognosis is, however, good, and the majority of patients, even those presenting severe symptoms, recover without operation.

6 *Streptococcal peritonitis*—Peritonitis due to the streptococcus is occasionally secondary to lesions of the alimentary canal, but much more frequently it is a sequel of puerperal infections. It occurs commonly after a first delivery, and is frequently associated with retained products. Infection takes place along the lymphatics of the damaged uterus or through the Fallopian tubes, and may be localised in the pelvis but more often produces peritonitis. The symptoms are characteristic and are associated with evidence of a marked septicæmia. The abdominal wall, being already greatly stretched, does not show the usual rigidity, and extreme distension occurs rapidly. Diarrhœa is commoner than constipation, and a high temperature with rigors is usual. The uterine discharges are offensive, the milk secretion is suppressed and the puerperals frequently die within the first week. This type of infection is more fulminant than any other, except certain cases of perforative peritonitis.

Diagnosis—The diagnosis of acute peritonitis is not usually difficult, except where the severity of the causal condition is so great that it masks the peritoneal response, or where the peritonitis occurs in a patient already so severely ill that no response is possible. Sometimes it is difficult to make a correct diagnosis of the lesion to which the peritonitis is secondary, and this may only be possible after laparotomy. The most valuable signs of acute peritonitis are the severe pain and tenderness, the rigid abdomen, the small, rapid and thready pulse, the dry tongue, vomiting and constipation, and the absence of sounds of gurgling on auscultation. Any of these symptoms may, however, be absent, and a diagnosis must be based on their occurrence in combination. In post-operative cases there is sometimes a remarkable absence of both pain and rigidity, and early recognition of the condition in these patients is often one of much difficulty.

Peritonitis is most likely to be mistaken for lead colic or acute intestinal obstruction. From the former it can be distinguished inasmuch as the abdomen in peritonitis is usually extremely tender, while, in colic, pressure often, though not invariably, relieves the pain, in lead colic a blue line on the gums is present, and the red corpuscles show punctate basophilæ, the pain is intermittent and there is usually no vomiting and less extreme rigidity. From acute intestinal obstruction the diagnosis is often far more difficult. In the early stages of obstruction, before peritonitis has developed, the intermittent nature of the pain, the absence of great tenderness or rigidity, the copious nature of the vomit and the evidence of increased peristalsis from inspection or auscultation should help to distinguish the two conditions.

In acute pancreatitis the pain is more definitely epigastric, the patient is usually over middle age and collapse is extreme. The menstrual history, the typical pallor and the results of vaginal examination usually serve to indicate a ruptured tubal pregnancy, and in other acutely painful abdominal conditions the localised nature of the pain and the absence of any extreme general tenderness help to distinguish the condition from peritonitis.

The gastric crises of tabes are seldom likely to be a source of error, but the comparative absence of severe symptoms in tabetics, the subjects of peritonitis, is apt to lead to a mistaken diagnosis.

Basal pneumonia and diaphragmatic pleurisy may lead to acute abdominal symptoms. The temperature and pulse, the raised respiration rate and a routine examination of the chest in all cases should prevent a mistake being made.

Prognosis.—The prognosis of acute peritonitis is always grave, even with early surgical treatment. Without operation no case of acute perforative peritonitis can be expected to recover; such exceptions as have been recorded must be regarded as medical curiosities.

In diffuse spreading peritonitis the outlook is still grave unless operation is undertaken; but the process is less rapid, and a small proportion of patients undoubtedly recover without surgical aid. These cases occasionally merge into a form of chronic fibro-purulent peritonitis, characterised by the progressive formation of collections of pus between neighbouring viscera, and by repeated outbursts of symptoms as other parts of the peritoneum become successively involved. This condition usually terminates in fatal septicaemia, with infections in the pleura, pericardium or endocardium. The prognosis in pneumococcal cases is considerably better, as even without operation a fair proportion recover, either with or without the formation of a hypogastric purulent collection. In the rare gonococcal cases recovery is the rule, and the fatal cases recorded have almost invariably followed operation.

In forming a prognosis chief reliance must be placed on the degree of toxæmia and the severity of the intestinal paralysis, and to a less extent on the degree of meteorism and the frequency of the vomiting. Spontaneous bowel actions or their induction by enemata make the prognosis relatively more favourable.

The rate of rise of the pulse-rate and its ratio to the temperature are also of importance; where there is a subnormal temperature throughout the issue is almost always fatal.

Treatment.—The principles that must underlie treatment are: (1) removal or limitation of the infective process to which the peritonitis is secondary. This almost always entails laparotomy; an occasional exception is in some instances of perforated peptic ulcer when further soiling may be prevented by suction of the stomach contents through an indwelling tube; (2) restoration of fluid loss by intravenous saline and glucose solutions; (3) adjustment of electrolyte balances; (4) measures to keep intestinal distension within limits, since severe distension may lead to permanent bowel paralysis and to death. This can usually be achieved by suction through indwelling tubes in stomach or bowel; such a tube naturally also prevents the discomfort and exhaustion of vomiting; its introduction before operation may prevent broncho-pneumonia from inhalation of post-operative vomit; (5) the administration of any appropriate antibiotics. Samples of the exudate or pus found at laparotomy should be sent to the laboratory for sensitivity tests.

Until a definite diagnosis has been made and operation advised and agreed to, the administration of opium in any form is contra-indicated. It masks the symptoms and by bringing to the patient and his advisers a false sense of security may lead to a fatal delay in undertaking the operation. When, however, a diagnosis has been made, and operation is agreed to, morphine is beneficial in reducing both the mental and physical symptoms while the necessary preparations are being made. Morphine as a method of treatment has been adopted more and more of recent years, the morphine being given deliberately and in doses sufficient to affect the respiration rate with the object of diminishing the activity of peristalsis, as well as of combating the shock, pain and restlessness, which help so largely to exhaust the patient's powers of resistance.

In pneumococcal cases there is not the same urgency for operation, and if the diagnosis can be made with certainty, adequate treatment with penicillin will produce a satisfactory result. In gonococcal peritonitis, if a diagnosis can be made, penicillin should also be resorted to; but if there is doubt, as there often must be, of the nature

of the infection, or if the patient shows any increase of symptoms, laparotomy is the only safe course to follow.

CHARLES DONALD.

CHRONIC PERITONITIS

Chronic peritonitis is a condition in which widespread and progressive chronic inflammation of the peritoneum occurs independently of tuberculous or malignant disease.

Ætiology.—Chronic non-tuberculous peritonitis may rarely occur post-operatively, as a result of irritation from particles of talc left from the powder on the surgeon's gloves. In a few cases it is without known cause, as in benign paroxysmal peritonitis (Siegal), which is thought to be allergic in origin.

In the majority of cases, however, chronic peritonitis is either due to a small tuberculous focus which has not been discovered or is part of a general disorder affecting other serous membranes. This, though not uncommon, is of unknown ætiology. It has been given a number of names and when affecting mainly the liver is called General Chronic Perihepatitis or Sugar-iced Liver; when affecting multiple serous membranes, Concato's Disease or Polyserositis; and when mainly the pericardium, Chronic Constrictive Pericarditis, Pick's Disease or Pericarditis Pseudo-cirrhosis of the Liver. The last condition, however, is usually tuberculous in origin (see p. 881).

Pathology.—The liver may be covered with a thick, hard and white coating of fibrous tissue, which can be peeled off to expose the smooth peritoneal surface. Perihepatitis is almost always associated with a similar thickening of the capsule of the spleen and with thickening of other parts of the peritoneum. Extensive general peritoneal adhesions are often present.

Symptoms.—The condition usually occurs in the young or middle-aged and is compatible with good health for a very long period. The most important and outstanding symptom is ascites. The onset is generally gradual, but it may be acute. Frequent tapping is required and the intervals between the performance of paracentesis tend to diminish and may finally be as short as a fortnight, when as much as a pint of fluid may be poured into the peritoneal cavity in a day.

Oedema, especially of the feet, is frequent in the later stages; it is generally cardiac or renal in origin, but may also be caused by pressure on the inferior vena cava, or an actual thrombosis.

The diagnosis from cirrhosis of the liver is suggested by the absence of jaundice, long history and frequent finding of constrictive pericarditis.

Course.—The course of the disease is very slow, death generally occurring from some intercurrent disease. The general health may remain good for a long time.

For the diagnosis and treatment, see Ascites (p. 721).

BILE PERITONITIS

The escape of bile into the peritoneum produces intense peritoneal irritation with symptoms of severe shock and rapid distension of the abdomen with fluid.

It is one of the most important complications that may follow needle biopsy of the liver; it also occurs after rupture of the gall-bladder and post-operatively when a stone has been overlooked in the common bile duct. In a few cases it appears to arise without any evidence of perforation or leakage from the gall bladder or bile ducts being found. It may remain an aseptic peritonitis or become rapidly infected and form turbid purulent fluid. Minor cases following liver biopsy may subside spontaneously, but in most other cases treatment is surgical.

TUBERCULOUS PERITONITIS

Ætiology—The peritoneum is involved in 15 per cent of fatal cases of tuberculosis. Tuberculous peritonitis is rare in infants and uncommon after 30, the majority of cases occur between the ages of 3 and 20. Boys and girls are equally liable to the disease, it is found much more frequently in women than men at operations, but more frequently in men than women after death.

Primary tuberculous peritonitis is uncommon in children and rare in adults. It is probably due to infection conveyed by the intestines, which do not themselves become infected. More often, especially in children, the mesenteric glands become tuberculous, generally without any lesion developing in the intestines, and the peritoneum is infected from the glands. In males the primary focus may be the prostate, vesiculæ seminales or testes, and in females the disease frequently begins in the Fallopian tubes, but the latter may also be infected from the peritoneum. Although tuberculous ulcers are found in the gut in over 50 per cent of fatal cases of pulmonary tuberculosis, the peritoneum is affected in only 4 per cent of cases. The peritoneum, the pleura and occasionally the pericardium may be involved together in the absence of any other tuberculous focus.

Pathology.—Tuberculous peritonitis may occur in three forms—the ascitic, loculated and obliterative.

1 In the ascitic form, which may be acute, subacute or chronic, miliary tubercles are scattered over the whole peritoneum, which is free or nearly free from adhesions. In chronic cases the tubercles are larger and more fibrotic than in the acute, the peritoneum is thickened and the mesentery is shortened so that the intestines are tethered to the posterior abdominal wall. This form may closely resemble malignant peritonitis, and large effusions may collect very rapidly.

2 In loculated tuberculous peritonitis the fluid may be clear, the condition being then intermediate between the ascitic and obliterative forms, or it may be turbid or purulent. In the latter case masses of tuberculous material separated from each other by adherent coils of intestine have broken down to form suppurating foci, which may erode the intestine or open at the umbilicus or even into the vagina.

3 Chronic obliterative, adhesive or fibrous tuberculous peritonitis may occur after absorption of fluid in the ascitic form or may develop primarily. No effusion is present, but universal adhesions obliterate the lumen of the peritoneum, all the viscera being inextricably bound together and to the parietal peritoneum.

In each form of tuberculous peritonitis the mesenteric glands are generally caseous ("tabes mesenterica") and may break down in the centre, the mediastinal glands may also become tuberculous. The omentum is often rolled into a solid mass, which sometimes contains caseous nodules.

Symptoms—Tuberculous peritonitis is sometimes completely latent, and may be discovered accidentally during an operation for some independent disease or for a hernia, when the sac may be the only part involved.

The onset of abdominal symptoms is generally preceded by a period of ill health. The patient loses weight and strength, his appetite is poor and his temperature may rise slightly at night. After a time he complains of general abdominal discomfort. Constipation is common, especially in the obliterative form. In other cases diarrhoea may occur owing to tuberculous ulceration of the intestines, fistulous communications between adjacent coils of intestines or simple enterocolitis. The stools are occasionally bulky owing to deficient absorption of fat caused by obstruction of the lacteals by caseous mesenteric glands (see p. 610). The spleen and less often the liver may be enlarged. The skin, especially over the abdomen, is dry, inelastic and sometimes so pigmented that Addison's disease is simulated. In chronic cases there is sometimes no pyrexia, more often the temperature is intermittently raised. In

acute and suppurative cases the temperature is generally high and irregular, and the pulse is rapid. Traces of albumin may be present in the urine owing to pressure on the renal veins caused by the large accumulation of fluid in the abdomen or to the effect of the toxæmia on the renal cells. A moderate degree of anæmia is often present, and leucocytosis develops if suppuration occurs.

In the ascitic form the abdomen gradually becomes distended. At first it is tympanitic, but after a time evidence of the presence of free fluid is obtained, but the quantity is often not very great. Less frequently a large amount of fluid collects with great rapidity and the sudden stretching of the abdominal muscles may cause a considerable amount of pain. Moderate tenderness of the whole abdomen is generally present. A large accumulation of fluid may compress the inferior vena cava and give rise to œdema of the legs. The diaphragm is pushed upwards and respiration becomes shallow and thoracic. The skin over the abdomen is shiny and the veins are enlarged. The ascitic fluid is generally clear and it often coagulates on standing. Less frequently it is turbid or blood stained. It always contains cells, a large proportion of which are lymphocytes. Tubercle bacilli are rarely found, although they must be present, as the fluid may produce tuberculosis when injected into guinea-pigs.

In the loculated form with suppuration the abdominal pain is generally greater. Attacks of colic are common, especially after exercise. The abdomen is distended and doughy. On percussion irregular tympanitic and dull areas are found. Large caseous glands and collections of pus between adherent coils of intestines may form palpable masses, which are immobile, tender and dull on percussion. The omentum can sometimes be recognised as a thick cord stretching across the upper part of the abdomen, the transverse colon generally forms a resonant band immediately above it, which helps to distinguish it from the lower edge of an irregularly enlarged liver. The ease with which the masses are felt varies from time to time with the amount of flatulent distension of the intestines. When an abscess is about to point at the umbilicus, the latter becomes indurated, red and tender. A similar condition is occasionally observed in pneumococcal peritonitis and in pelvic peritonitis in women. On rectal and vaginal examination thickened Fallopian tubes, enlarged glands or collections of pus may be felt.

The signs of obliterative tuberculous peritonitis are ill defined. The abdomen gives a characteristic rubbery resistance on palpation and is generally somewhat distended. Irregular masses may be felt in it, and the peristaltic waves of the small intestines are often visible, especially in children. This does not necessarily indicate that partial obstruction is present, as it may be simply a result of the abnormal thinness of the abdominal wall.

Symptoms of tuberculous disease of other organs, especially of the lungs, pleura and intestines are often present. Generalised tuberculosis may develop at any time, especially in children. Vomiting and constipation which suggest intestinal obstruction, may be the first symptoms of tuberculous meningitis.

In rare cases acute peritonitis may develop as a result of rupture of a softened caseous gland or perforation of a tuberculous ulcer.

When a patient recovers from tuberculous peritonitis, the tubercles and adhesions may completely disappear. More frequently localised adhesions remain, and calcified tuberculous mesenteric glands are often found with the radiograph, at operations and after death. They may give rise to confusion when the abdomen is radiographed on account of suspected renal calculi. They do not, however, move with the shadow of the kidney with changes in posture, and the diagnosis can always be settled by pyelography. The bands, which may form from localised adhesions occasionally cause acute intestinal obstruction, sometimes not until many years after the active disease has disappeared.

Diagnosis—In the presence of tuberculous disease of the lungs or other organs,

abdominal distension, especially if associated with ascites or irregular abdominal masses, generally indicates that tuberculous peritonitis is present. The discovery of tubercle bacilli in the sputum, and their much less common discovery in the faeces or vaginal discharge, is very strong confirmatory evidence. Ascites in children and in females with symptoms pointing to tuberculous salpingitis is generally due to tuberculous peritonitis.

Acute cases may at first closely simulate pneumococcal peritonitis or even appendicitis; but in non-tuberculous inflammatory exudates of the peritoneum most of the cells are polymorphonuclear leucocytes instead of lymphocytes. Ascites due to cirrhosis of the liver in children is almost always mistaken for tuberculous peritonitis; on the other hand, the ascitic form of tuberculous peritonitis in middle-aged alcoholic individuals is likely to be mistaken for ascites due to cirrhosis. When cirrhosis is undoubtedly present, ascites may still be due in part to tuberculous peritonitis; a large proportion of lymphocytes in the fluid is very strong evidence in favour of this, as the ascitic fluid in uncomplicated cirrhosis contains few except endothelial cells. In simple chronic peritonitis there is no fever and little or no pain, and the ascitic fluid contains few if any lymphocytes. The presence of irregular masses together with fluid in the abdomen generally indicates tuberculous peritonitis in children; but it is more frequently due to malignant disease in adults, especially in males. The history of the case and any evidence of tuberculous or of malignant disease in other parts of the body help to settle the diagnosis.

Fever, inflammation of the umbilicus, and the presence of lymphocytes in the ascitic fluid point to tuberculosis, whilst nodular infiltration without inflammation of the umbilicus, hard and enlarged glands in the groin or neck, and the presence of large, multinuclear cells or groups of cells in the effusion point to cancer.

Prognosis.—Before the advent of chemotherapy recovery took place in a large proportion of cases of the ascitic form of tuberculous peritonitis. When localised abscesses developed complete recovery was rare, and when a faecal fistula formed death almost always followed. Prolonged fever, rapid emaciation and intractable diarrhoea were the most serious symptoms. Apparent recovery was sometimes followed by a relapse, generally owing to reinfection from an unhealed primary focus, such as a tuberculous gland, appendix or Fallopian tube.

Treatment.—The principles of treatment are the same as for tuberculosis in general (see p. 1031). Complete bed rest and a nutritious diet are essential and chemotherapeutic drugs should be given for at least 3 months. Streptomycin 1.0 g. intramuscularly daily can be combined with oral isoniazid 100 mg. twice or three times daily. Diarrhoea should be treated by a non-irritating diet, and in intractable cases by opium preparations. If fatty diarrhoea is present, fat must be excluded from the diet. With this exception, the food should be as abundant and nourishing as possible.

When the abdominal distension in ascitic cases gives rise to discomfort paracentesis should be performed. The occurrence of intestinal obstruction is an indication for operation, though it may not be possible to do anything useful owing to the extensive adhesions present and the danger of tearing the intestines. Laparotomy is not indicated for ascites alone, though it is sometimes followed by surprising improvement in the condition.

CANCER OF THE PERITONEUM; MALIGNANT PERITONITIS

Ætiology.—Cancer of the peritoneum is almost always secondary. The primary disease is generally in the abdomen, especially the stomach and the ovary, the peri-

toneum becoming involved by spread along lymphatics or blood vessels, by direct contact, or most commonly by malignant cells being set free and scattered widely over the peritoneum. The disease may also spread from cancer of the breast by the deep lymphatics of the chest and abdominal wall, and by lymphatics from malignant disease of the testis.

Pathology.—Malignant deposits may form minute tubercles, larger white non-cascating nodules or even very large masses. The parts most generally involved are the omentum, mesentery and pelvis. Chronic fibrotic changes frequently occur, and result in the omentum being rolled up and the mesentery shortened as in tuberculous peritonitis. The diaphragm is often invaded with growth, which spreads to one or both pleuræ. Acute or subacute peritonitis may occur.

Symptoms.—The symptoms are caused in part by the primary disease and in part by the secondary malignant peritonitis. As the former is generally situated in the abdomen, it is impossible to distinguish between the symptoms due to the two causes. Malignant peritonitis generally results in ascites; the fluid is often blood-stained, but may be clear or turbid, or less frequently chylous owing to obstruction and subsequent rupture of lacteals. The umbilicus is often infiltrated with growth, and nodules may be felt along the falciform ligament. Tumours are often felt in the abdomen or on rectal examination; they are sometimes too small to be palpable, and in other cases they can only be felt after the fluid has been removed. The rolled-up omentum may be recognised as a thick transverse cord above the umbilicus. The malignant masses or peritoneal adhesions may give rise to obstructive symptoms.

Diagnosis.—The development of new abdominal tumours or ascites in a patient who is known to have cancer of the stomach or other organ is almost conclusive evidence that the peritoneum is involved. When there is no clear evidence pointing to the presence of a primary malignant or tuberculous focus, it may be difficult to distinguish between tuberculous and malignant peritonitis (see pp. 718, 720). When ascites is present and no tumour is palpable, currhosis, heart failure, simple chronic peritonitis or portal thrombosis may be simulated, the abdomen should be tapped, when a tumour often becomes palpable if malignant disease is present.

Prognosis and Treatment.—It is rare for the patient to survive for more than 6 months after the peritoneum becomes involved. Treatment is purely palliative. Considerable relief may follow paracentesis

ASCITES

Definition.—Ascites is the accumulation of free fluid in the peritoneal cavity.

Ætiology.—Ascites is a constant symptom of simple, tuberculous and malignant chronic peritonitis. It occurs when there is a rise of pressure in the portal circulation; it is always present in portal thrombosis and when the portal vein is obstructed by a growth or an aneurysm, and portal obstruction is in part responsible for its presence in cirrhosis of the liver. Ascites is very common in heart failure, in which it is almost always associated with œdema of the feet. It is in part due to the same causes as the œdema, but it is also in part caused by portal congestion, and by obstruction to the lymph flow from the thoracic duct owing to the rise of venous pressure. Lastly, ascites accompanies the dropsy of Bright's disease and severe anæmias, largely as a result of the hypoproteinæmia which is present.

Symptoms.—The abdomen becomes gradually enlarged, at first in an antero-posterior direction, the costal margin being pushed forward, but at a later stage the bulging occurs in the flanks also. The stretching of the abdominal wall gives rise to a tight sensation, which may amount to actual pain if the fluid collects rapidly. It causes the muscles to atrophy and linea atrophica develop in the skin. The umbilicus becomes everted and may form a thin-walled bladder.

The rise in intra-abdominal pressure caused by the accumulation of ascitic fluid presses on the inferior vena cava; œdema of the legs may occur, and the obstruction to the renal circulation may cause albumin to appear in the urine, the quantity of which is reduced owing to the loss of water in the ascitic fluid. Compensatory dilatation of other venous channels results: the dilatation of the veins passing between the abdominal wall and those in the falciform ligament is manifested by the development of large and prominent subcutaneous veins around and above the umbilicus; others pass from the superficial and deep epigastric veins in the middle of the groin towards the costal arch, where they join the superficial epigastric and long thoracic veins. When paracentesis is performed, the dilated veins disappear if they have developed as a result of pressure on the inferior vena cava, but not if obstruction of portal veins is the primary condition.

The diaphragm is pushed up; its excursions on respiration are reduced and dyspnoea may result. The impulse of the heart may be felt in the third intercostal space; the twisting of the heart may temporarily produce a pulmonary systolic murmur. Cardiac irregularity, palpitation and attacks of faintness may follow. The upper border of hepatic dullness may reach the fourth, third or even second intercostal space in front; the right base is dull behind owing to the liver being pushed up and the lung compressed. A pleural effusion may be suspected, but the upper limit of dullness is altered on taking a deep breath if it is due to the liver being pushed up, and the increased dullness diminishes or disappears when the patient lies on his face; in pleural effusion the dullness is higher in the axilla than behind, but this is not the case if it is due to an abnormally high position of the liver.

The pelvis and renal regions hold a considerable amount of fluid, so that no accumulation occurs in the flanks until at least a litre is present in the abdomen. As more fluid collects, the resonant note in the flanks is replaced by dullness, but the change may be delayed if there is much gas in the colon. The level of dullness now gradually rises and spreads over the pubes towards the umbilicus. On turning from one side to the other the most dependent part remains dull. Such shifting dullness may not be easy to elicit but when present is almost pathognomonic of ascites; very similar movable dullness may, however, rarely occur in chronic obstruction of the small intestines when they are distended with fluid faeces and gas.

In chronic peritonitis the mesentery may be so shortened that the intestines are unable to float on the fluid; the fluid then accumulates in front of the intestines, and the highest part of the abdomen is dull.

A characteristic fluid thrill is felt when one side of the abdomen is sharply flicked by the fingers of one hand, whilst the other hand is placed flat upon the opposite side of the abdomen. When the patient is very fat or the abdominal wall is œdematous, a similar but less marked sensation may be produced. In doubtful cases the hand of an assistant should therefore be pressed perpendicularly over the middle line of the abdomen, as this prevents the transmission of the impulse through the abdominal wall, but not through the fluid contents of the abdomen.

When the liver or spleen is enlarged and hard, or when an abdominal tumour is present, the sensation produced by dipping the tips of the fingers suddenly through the fluid on to the solid organ, which jumps away from them, is most characteristic.

Diagnosis.—The presence of ascites must first be distinguished from other causes of abdominal enlargement such as meteorism, pregnancy and obesity. A distended bladder, a very large hydronephrosis, or a big pancreatic or mesenteric cyst may sometimes cause confusion, as may more particularly, a large ovarian tumour. The history of the development of the abdominal swelling may help the diagnosis. In the case of an ovarian tumour, the outline of the tumour can frequently be definitely felt, and its pelvic attachments can be recognised by vaginal examination. The antero-posterior enlargement is greater than the lateral bulging, whereas the reverse is the case in ascites; the maximal girth is below the umbilicus instead of at the

umbilicus or above, the umbilicus which is normally and in ascites an inch nearer the pubes than the ensiform cartilage, is proportionately farther from the pubes, and the distension on one side is often greater than the other instead of being uniform.

Diagnosis of Cause of Ascites—In cirrhosis of the liver the fluid collects rapidly and the patient often appears ill and wasted. In chronic peritonitis the accumulation on the first occasion is generally gradual and the patient may be otherwise well. An enlarged spleen or the occurrence of hæmatemesis points to cirrhosis. A patient with ascites due to cirrhosis alone rarely survives the performance of paracentesis more than a few times, as his general health has often greatly deteriorated by the time that ascites develops, but this is much less true in chronic peritonitis. Tuberculous peritonitis is uncommon over the age of 30, except as a complication of cirrhosis of the liver and when secondary to tuberculous Fallopian tubes. Evidence of tuberculous disease in other parts of the body, solid masses palpable in the abdomen or on rectal examination, pain and tenderness in the abdomen except over the liver, and induration and redness of the umbilicus point to tuberculous peritonitis, the fluid is generally turbid, the specific gravity is above instead of below 1.015, and lymphocytes are present.

In malignant peritonitis there is generally evidence of the primary disease in some other organ, and nodules may be felt in the abdomen, in the neighbourhood of the umbilicus, or in the middle line above it, and enlarged glands may be present. The spleen is not enlarged. Emaciation is generally greater than in cirrhosis, and, except when the primary disease is in the stomach, there is no hæmatemesis. Rectal and vaginal examinations are particularly important as ascites, which may recur very frequently, sometimes results from ovarian tumours. In a doubtful case the diagnosis may become clear after paracentesis, when the large hard liver and spleen may be felt in cirrhosis and an irregular enlargement of the liver, but no splenomegaly, in cancer of the liver. In malignant disease the fluid may contain cancer cells, it is more often hæmorrhagic than in tuberculous peritonitis or cirrhosis.

Rapid development of ascites with enlargement of the spleen and sometimes hæmatemesis suggests portal thrombosis. If symptoms pointing to cirrhosis are already present, it is probably secondary to this, and even in their absence it may be secondary to latent cirrhosis.

An examination of the circulatory system and the urine should prevent confusion between ascites due to cirrhosis and that due to heart failure or kidney disease, but these conditions may be associated.

An additional method of diagnosis in ascites is the direct inspection of the abdominal viscera, a procedure known as laparoscopy or peritoneoscopy. After the abdomen has been tapped for the removal of fluid 2 or 3 litres of air are introduced. The abdominal wall is punctured by a large trocar and cannula and through the latter the instrument, which is similar to the cystoscope, is passed into the pneumoperitoneum. By this means it is possible in the majority of patients to inspect the anterior aspects of the liver and stomach, the anterior parietal peritoneum, the omentum, parts of the small intestine and the superior aspects of the pelvic organs in female patients. It is sometimes possible to see the gall bladder, parts of the large intestine, the appendix, hernial orifices and the spleen when enlarged. Laparoscopy may sometimes enable the physician to make a reasonably certain diagnosis of cirrhosis of the liver, carcinoma of the stomach, malignant metastases in the liver, peritoneum and omentum, and various other conditions, but its value in diagnosis has proved disappointing.

Treatment—Paracentesis should be performed if the accumulation of fluid causes serious discomfort or greatly interferes with the digestion, circulation or respiration. Hæmatemesis is a further indication, as paracentesis reduces venous engorgement. The trocar should be inserted in the middle line between the umbilicus and pubes or in the flank. Care must be taken to avoid the bladder, or the liver or

spleen if they are very much enlarged. A trocar and tube of moderate bore should be used, as the very fine Southey's tubes tend to become blocked and the discomfort caused by the paracentesis is needlessly prolonged.

A salt free diet should be given, as ascitic fluid never contains less than 8 g of sodium chloride in each litre and if the quantity of salt taken in the day is reduced to 0.8 g, less than 100 ml of ascitic fluid can collect during the same period.

Alternatively mercurial diuretics can be prescribed, *e.g.* injection of mersalyl B.P. 2.0 ml intramuscularly, once or twice weekly. Diuretics are more valuable as preventatives when the fluid first appears or after it has been removed than as curatives when a large quantity is present, as the pressure on the renal veins makes the kidneys less active, and an enormous quantity of fluid has to be excreted by them before the accumulation can disappear, whereas comparatively little urine need be passed to prevent re-accumulation of ascitic fluid after tapping.

The bowels should be kept well open, but severe purging weakens the patient and is likely to aggravate the catarrh of the alimentary canal which is often already present. Lysol salts, which also promotes biliary drainage, is the most suitable aperient. High protein diet is indicated if the serum protein is low and especially if ascitic fluid has to be removed, since one paracentesis alone may mean the loss to the body of over 200 g of protein if fresh fluid reforms.

For the surgical treatment of cirrhosis, see p. 679.

THOMAS HUNT

SECTION IX

DISEASES OF THE BLOOD

THE blood is sometimes regarded as the mixed secretion or product of the blood-forming organs. For the purposes of description and for the better understanding of the changes in disease, it is more convenient to think of the blood and blood-forming organs as composed of three distinct systems or tissues: (1) the red cells and their precursors, sometimes known as the erythron; (2) the white cells and the immature cells from which they arise; (3) the platelets and the megakaryocytes. These three systems of cells exist side by side in the plasma and bone-marrow, and are often affected simultaneously by disease, but they are to a large extent independent of each other. Before discussing separately the three systems of cells and their diseases, it will be convenient to say a few words about the total volume of the blood.

THE BLOOD VOLUME

The total volume of the blood is about 90 ml. per kg. of body weight, *i.e.* some 6,000 ml. in an average individual, or about one-eleventh of the body weight. Rather lower values are given by recent techniques. Of this volume the cells constitute about 42 per cent., the remainder being plasma. The blood volume is moderately diminished in anæmia; it is moderately increased in the splénomegalies, in leukæmia and in erythrocytosis, and greatly increased, even to twice the normal, in erythræmia. There is a slight increase in œdema, due to an associated œdema of the blood, but no change in arterial hypertension. The blood volume is moderately increased in pregnancy, in order to allow for the fetal circulation. Of great importance in practice are the conditions in which the volume of circulating blood is suddenly and considerably diminished. Hæmorrhage, external or internal, is the commonest cause of a fall in the blood volume, but the blood volume may be reduced by loss of plasma alone in crushing injuries, burns, anaphylaxis and the dehydration associated with alkalosis, diabetic coma, cholera and severe infections. Symptoms of shock quickly appear. In acute anæmia from hæmorrhage or blood destruction there is extreme exhaustion, faintness or syncope, air-hunger, sweating and thirst. The degree of shock depends largely on the rate of bleeding. A sudden hæmorrhage of 1500 to 2000 ml. may be fatal, while as much as 60 per cent. of the total amount of blood may be lost without death if the hæmorrhage is prolonged over 24 hours or more. The other important factor which determines the degree of shock is the extent of any associated injuries. The blood count is of limited value in determining the patient's condition, for hæmodilution may take 2 to 3 days and hæmoglobin values around 13 g. (90 per cent.) are the rule within the first hour of sustaining injuries, no matter how severe the patient's hæmorrhage has been. In alimentary hæmorrhage the blood urea may be raised, owing to absorption of the effused blood, and the height of the rise is a fair measure of the severity of the bleeding.

In acute reduction of blood volume from any cause a systolic pressure below 80 mm. of mercury, a progressive increase in pulse-rate and the development of crepitations in the lungs are all serious signs. The patient becomes collapsed, complains of thirst, the skin is pale, cold and moist, the breathing quick and shallow, the pulse rapid and almost imperceptible, and the blood pressure low. The kidneys are inadequately supplied with blood and the output of urine may almost cease. The symptoms are often mistaken for heart failure, but there is no orthopnoea, venous

engorgement or œdema, and they are really due to loss of fluid from the circulation and stasis of blood in the capillaries.

The logical *treatment* in all forms of shock is to increase the blood volume and the venous return to the heart in any way possible. The foot of the patient's bed may be elevated, the legs bandaged from the ankles to the mid-thigh and the intake of fluid by the mouth increased, unless these measures are otherwise contra-indicated. A careful watch should be kept on the output of urine, suppression of urine being particularly likely to occur in crush injuries. The patient should be kept warm, but not too warm, and inhalation of oxygen or oxygen plus carbon dioxide may be helpful. Apart from sedatives for pain, drugs are of little value. Various types of infusor have been used with the object of restoring the blood volume to normal and it has thus been discovered that whole blood, plasma and serum are the most satisfactory fluids. Solutions of saline or dextrose produce only transient improvement. Blood is the fluid of choice when there has been much bleeding, though in urgent cases it may be desirable to begin treatment with plasma or serum to save time in typing and cross-matching. Plasma or serum is the fluid of choice where there is hæmoconcentration, as in burns. Plasma and serum must be obtained from human blood donors, and they may give rise to homologous serum jaundice. Efforts have therefore been made to replace them by synthetic colloidal solutions, of which dextran and polyvinylpyrrolidone are recent examples, but solutions of this kind must be regarded as still on trial. Transfusion must be begun at the earliest possible moment to prevent the patient relapsing into an irreversible state, and it must be continued until the blood pressure is raised to what can be regarded as a normal level. Up to this point it should be given as rapidly as possible, but thereafter it should be slowed to a drip and maintained at this level until the conclusion of operative or other treatment. If a patient is bad enough to require transfusion, he will usually require at least 1500 ml. of blood or plasma.

THE RED BLOOD CELLS

The red blood cells are biconcave discs with a mean diameter of 7.20 microns (6.7 to 7.7 μ), a mean volume of 85 cubic microns (75 to 95 $\mu\mu$), and a mean corpuscular hæmoglobin content of 29 micromicrograms¹ (26.5 to 31.5 $\gamma\gamma$). Their size and shape are adapted to the carriage of hæmoglobin and the supply of oxygen to the tissues. The blood of a healthy young male contains about 5.5 millions of red cells per c.mm. and 16 g. of hæmoglobin per 100 ml.; of a healthy female about 4.75 millions of red cells per c.mm. and 14 g. of hæmoglobin per 100 ml. The normal range of variation of the erythrocyte count is from a million above to a million below the average male value, i.e. any figure between 4.5 and 6.3 million red cells per c.mm. may be considered normal, and there is naturally a corresponding fluctuation in the hæmoglobin percentage. A hæmoglobin percentage below 12.5 g. (85 per cent) is always abnormal, though symptoms of anæmia rarely appear until the hæmoglobin falls below 11 g. (75 per cent.). Erythrocytes and hæmoglobin are subject to much less diurnal variation than the white cells, but significant changes may occur after exertion. For purposes of calculation the normal red cell count is taken as 5 million cells per c.mm., and the corresponding amount of hæmoglobin (14.8 g. per 100 ml. of blood) is taken as 100 per cent. hæmoglobin. The *colour index* measures the average amount of hæmoglobin contained in the red corpuscles of a sample of blood, and is calculated from the formula

$$\text{Colour index} = \frac{\text{Hæmoglobin per cent.}}{\text{Number of red cells per cent. of the normal.}}$$

¹ A micromicrogram is the millionth of a millionth part of a gram (1 g. $\times 10^{12}$), and is abbreviated by the Greek letters gamma ($\gamma\gamma$).

The red cells in any sample of blood are never absolutely equal, but show a certain amount of variability in size, or *anisocytosis*. The degree of variability, or anisocytosis, is often increased in anæmia and may be of diagnostic significance. The mean diameter of the red cells and their variability is determined by measuring the diameter of 500 successive red cells under the microscope on a stained thin smear. The results are then plotted on squared paper, with the number of cells counted as ordinates and the diameter of the cells as abscissæ, to obtain what is known as a red cell diameter distribution curve, or Price-Jones curve (Fig. 1). Abnormal variability in the size of the cells will be shown by a widening of the base of the curve. Cells which are larger than normal and fall to the right of the limits determined on healthy individuals are called *macrocytes*. Small cells which fall to the left of the limits of health are called *microcytes*. A cell of normal diameter is a *normocyte*. The cell volume is obtained by centrifuging a sample of blood under standard conditions; the mean cell volume is calculated from the height of the column of red cells and the total red cell count. As the red cells age, they become malformed and finally broken into fragments which are engulfed by the phagocytic cells of the liver, the spleen and other tissues. These malformed red cells are called *poikilocytes*. In all forms of anæmia the cells put into circulation are less perfect than in health, and poikilocytosis more rapidly develops.

If a sample of citrated blood is allowed to stand, the red cells will aggregate and fall out of suspension. This is a complex phenomenon but the chief factors are the concentration of the red cells and the constitution of the plasma; anæmia and increases in globulin and fibrinogen tend to accelerate the fall. The *erythrocyte sedimentation rate* is increased in pregnancy, infections and malignant disease.

Blood groups.—In the year 1900 Landsteiner and his pupils made the surprising discovery that the red cells of mankind are not immunologically identical, and that the sera of many people contain antibodies which agglutinate and destroy the red cells of others. There are, in fact, four main blood groups, which are determined by the presence or absence of two agglutinogens, A and B, of which either may be present separately (groups A and B), neither may be present (group O), or both may be present together (group AB). Corresponding to these two agglutinogens are their homologous antibodies or agglutinins—anti-A (or α) and anti-B (or β)—which are present in the serum in reciprocal relationship to the agglutinogens of the cells. The following table illustrates the Landsteiner classification of blood groups and the distribution among the population in England.

It can be seen that the serum of group AB will not agglutinate the red cells of any other group, and for this reason group AB has been called "universal recipient". For similar reasons members of group O are called "universal donors", because their red cells contain no agglutinin; but blood from group O should only be transfused into members of other groups in extreme emergency; whenever possible patients should be transfused with their own group. It has been shown by a number of observers that the ABO blood groups have sub-groups, and interaction may occur between members of the same group. The existence of agglutinogens A_1 and A_2 is now generally accepted. For this reason the compatibility of donor and recipient must always be confirmed by direct cross-matching of the cells of the donor and the serum of the recipient.

The four groups A, B, AB and O constitute the ABO blood-group system. It is now known that there are a number of other blood-group systems and these are of great importance in genetics, anthropology and criminology. They are important clinically only in so far as the relevant antibodies may cause trouble during transfusion, when hæmolytic may occur, or during pregnancy, when antibodies may cross the placenta of the mother and damage the fœtus. The only blood-group systems which commonly give rise to trouble in this way are the ABO and the Rh systems. In selecting donors it is necessary to pay attention only to the ABO and Rh systems, but because

of the other systems compatibility tests must be carried out with special care in patients who have had previous transfusions and may thereby have been stimulated to produce abnormal antibodies. The Rh system contains a number of "para"

Blood Group	Agglutinin	Agglutinogen	Per Cent
AB	None	A and B	3
A	<i>b</i>	A	42
B	<i>a</i>	B	9
O	<i>a</i> and <i>b</i>	None (0)	46

FIG. 1.—Frequency distribution curves of red cell diameters in health and disease (Price Jones curves)

blood groups in the same way as the ABO system, but their nomenclature and determination are a matter for the expert. In routine clinical work it is sufficient to classify people as Rh positive (83 per cent.) and Rh negative (17 per cent.) according to their reaction to a serum which was originally prepared by injecting the red cells of Rhesus monkeys into rabbits. People whose erythrocytes are Rh negative are capable under certain circumstances of forming an antibody which reacts with the

Rh antigen. This may occur after transfusion of Rh-positive blood, but it more commonly happens when a woman who is Rh-negative becomes pregnant with a child whose erythrocytes are Rh-positive.

Experience has shown that grouping is not necessary when serum or plasma is transfused. This is partly because the serum or plasma which is administered is usually a pooled product from a number of patients, but more important is the fact that the group antigens are not confined to the red cells but are present also in the body fluids and other tissues, and absorption of antibody by these agencies serves to protect the recipient's red cells from agglutination when a potentially dangerous plasma is administered. This latter fact also explains the infrequency of symptoms when group O blood is transfused into patients of other groups, inasmuch as the α and β agglutinins in the plasma are not merely diluted, but to a large extent neutralised in the circulation of the recipient. Nevertheless, it should be the rule nowadays, when blood is transfused, to use only blood of the same ABO and Rh group as the recipient, owing to the risks in a subsequent transfusion or pregnancy when this rule is broken. The same rule applies to the intramuscular injection of blood.

Nomenclature.—The red cells are formed in the bone-marrow, which can be examined during life by the techniques of sternal puncture and marrow biopsy. The nucleated precursors of the red cells in the marrow are known by the generic name of *erythroblasts*. In normal marrow the erythroblasts are *normoblasts*, which subsequently develop into normocytes, but in certain diseases larger forms with more primitive nuclei are found, the *megaloblasts*, which give rise to megalocytes. The nucleated red cells lose their nuclei by extrusion or solution, but for a time they still contain remnants of the original basophil cytoplasm, which gives the red cell a bluish tinge in ordinary stained smears (*diffuse basophilia* or *polychromasia*). Certain dyes, such as brilliant cresyl blue, when brought in contact with the fresh-drawn blood, precipitate this basophil cytoplasm in a network or reticulum, and on this account these immature red cells are called *reticulocytes*. Polychromasia and reticulocytosis are identical conditions revealed by different stains. The normal reticulocyte count is $\frac{1}{2}$ to 2 per cent. A similar precipitation may occur *in vivo* when poisons, such as lead, circulate in the blood-stream and the reticulum becomes visible in ordinary preparations (*punctate basophilia*).

Blood diseases may be due to causes originating outside the blood-stream and the bone-marrow and on this account we refer to many of them by names which merely describe the type of reaction or blood picture. Thus, anæmias may be described as hæmorrhagic, hæmolytic or aplastic in type. According as the colour index is high, normal or low, they are described as *hyperchromic*, *orthochromic* or *hypochromic*. They can also be classified by the size of the red cells into *macrocytic*, *normocytic* and *microcytic* anæmias. These two sets of terms correspond roughly with each other, but they are not absolutely interchangeable, and each should be used strictly according to definition. The description *megalocytic* is best confined to cases of anæmia in which the marrow is megaloblastic.

THE SYMPTOMATIC ANÆMIAS

Synonym.—Secondary Hypochromic Anæmia.

Definition.—A symptomatic anæmia is one which arises in the course of some other well-defined disease. The colour index is usually low and hardly ever above unity. In the rare cases in which the colour index rises above unity, the disturbance of the erythropoietic tissues is usually so profound that for practical purposes all the megalocytic anæmias can be regarded as actual diseases of the erythropoietic tissues.

Ætiology.—The most obvious cause of anæmia is hæmorrhage: acute hæmorrhage occurs most commonly from trauma, bleeding from the alimentary tract and

the accidents of childbirth; chronic hæmorrhage is often due to hæmorrhoids, menorrhagia and, in tropical countries, hookworm disease. Hæmolysis is a rare event, but it may be induced by chemical poisons, such as sulphanilamide and arseniuretted hydrogen, or by infection by hæmolytic organisms, such as the *Streptococcus pyogenes* or the *Clostridium welchii*, or by malaria. Acute infections rarely produce much anæmia, but severe anæmia may develop in protracted septic infection, acute rheumatism, rheumatoid arthritis and other subacute or chronic infections, such as typhoid fever. Focal sepsis is seldom responsible for an anæmia. Tuberculosis causes little anæmia until the later stages, when hæmorrhage, suppuration or intestinal ulceration have occurred. Syphilis also is rarely the cause of anæmia, except in the more florid stages, from involvement of the liver, or from paroxysmal hæmoglobinuria. Malaria has already been mentioned. Of the toxæmias responsible for anæmia, nephritis and lead poisoning are the most important. Malignant disease is one of the commonest causes of anæmia; it may act in various ways—hæmorrhage from a malignant ulcer, cancerous cachexia, and invasion of the bone-marrow. Anæmia which is due to mechanical limitation of the bone-marrow by tumours or tumour-like conditions, such as leukaemia, Hodgkin's disease, infective granulomata and kala-azar, is sometimes described as myelophthisic anæmia, but this is an incorrect and unnecessary use of a word which is one of the synonyms for aplastic anæmia.

Pathology.—Two factors can be distinguished in these symptomatic anæmias. The first is loss of blood by hæmorrhage or hæmolysis. This leads to hyperplasia of the bone-marrow, and an outpouring of new red cells to repair the deficiency. The colour index is low, because hæmoglobin regeneration lags behind the restoration of a normal cell count, and the reticulocyte count is increased to 5 or 10 per cent., or higher. Chronic and repeated hæmorrhage may so exhaust the hæmatinæ reserves that the body cannot repair the hæmoglobin deficiency, the anæmia remains torpid and the reticulocyte count is low; rapid recovery occurs on the exhibition of large doses of iron. The second factor in the symptomatic anæmias is depression of the erythropoietic tissues by toxæmia. Hæmopoiesis may be inhibited without much structural alteration in the marrow, but in other cases the marrow becomes hypoplastic and may even degenerate completely. The output of new red cells is diminished, the reticulocyte count is low and the colour index a little below unity. Usually increased blood destruction and diminished blood formation are present in varying degree, and the blood picture is modified accordingly. The white cells and platelets are normal or increased in number, unless the marrow is greatly depressed. The other tissues generally show anæmia, œdema and fatty change.

Symptoms.—The symptoms, other than those of the primary malady, depend on the speed with which the anæmia develops, and in acute anæmia from hæmorrhage or blood destruction there may be actual shock. In chronic anæmia, on the other hand, it is surprising how well the patient may feel and no complaint may be made with a hæmoglobin of 40 per cent. Inquiry elicits such symptoms as dyspnoea, palpitations, anginal pain, fainting attacks and œdema of the extremities. The pallor is best seen in the conjunctivæ or the palate; the skin is a bad guide, for it is often pale when there is no anæmia, and sunburnt and deceptively healthy when anæmia is severe. The pulse is rapid and the heart dilated, and systolic murmurs may be audible over the præcordium.

Diagnosis.—The cause of a symptomatic anæmia may be obvious, but on the other hand, it may demand the most searching overhaul of the patient with all the resources of a modern hospital. Attention should be particularly focused on the alimentary tract, as conditions such as diaphragmatic hernia, peptic ulcer, carcinoma of the stomach or bowel, polypi and hæmorrhoids may exist with no other symptom than anæmia.

Prognosis and Treatment.—The prognosis and treatment are those of the primary disease. In acute anæmia the patient should be transfused if his condition

is critical. In chronic hæmorrhagic anæmia iron is of great value. In the majority of the symptomatic anæmias it is possible to produce a normal blood picture for a time by transfusion, and so bring the patient into condition for operation or similar treatment, but iron and liver have little effect if the cause of the anæmia is not removed.

THE DEFICIENCY DYSHÆMOPOIETIC ANÆMIAS

An important group of anæmias is due to a defective supply of raw materials for blood formation. As these anæmias are the result of a disturbance in the growth of the red cells, they are called *dys hæmopoietic*. Absence of cyanocobalamin or folic acid gives rise to a megaloblastic reaction in the marrow, the megalocytes which result are treated by the body as abnormal cells, and anæmia develops which is in part due to disturbance of blood formation, in part to increased destruction. Iron and traces of copper are needed for the manufacture of hæmoglobin. The balance between the absorption of iron and the needs of the organism is a delicate one and it easily breaks down under conditions of malnutrition or the demands of growth and reproduction. In these circumstances hæmoglobin production becomes defective and a hypochromic anæmia develops. There is no hæmolytic component in the anæmia of iron deficiency. Vitamin C and thyroxine are also essential for blood formation. In their absence there is a general decline of hæmatopoiesis, rather than a specific variation from the normal. Both the latter conditions are frequently complicated by hæmorrhage and iron deficiency, but if this does not happen, hypothyroidism may produce a macrocytic anæmia which closely mimics pernicious anæmia. Lack of protein is an important factor in the anæmia of malnutrition, though it is usually complicated by other defects in the diet. The dys hæmopoietic anæmias are frequently associated with glossitis, gastro intestinal disorders and degeneration of the nervous system. The reticulocyte count is low, and the white cells and platelets are normal or diminished. Remission of the disease is attended by an outpouring of reticulocytes in numbers directly proportional to the extent of the hyperplasia of the bone marrow. This is called the *reticulocyte crisis*.

1 ANÆMIA OF IRON DEFICIENCY OF INFANTS

Synonyms—Nutritional Anæmia of Infants, Anæmia of Prematurity.

Anæmia of moderate degree is present in practically all infants whether fed by the breast or artificially. It may become very severe, especially in twins and premature babies, who come into the world with a small store of iron or after intercurrent infection, or when suckling is protracted beyond the normal period. It disappears spontaneously on the adoption of a mixed diet, and it appears to be a pure mineral deficiency, resultant from the low iron and mineral content of the milk, and reparable by inorganic salts of iron. In severe cases the hæmoglobin is reduced to 5 g (30 per cent) or less. The colour index is low. Death may occur, especially when the anæmia is exacerbated by intercurrent infection. Repair of the anæmia is followed by increased resistance to infection. Treatment is by iron and ammonium citrate, in a dosage of gr $4\frac{1}{2}$ to 9 daily. Ferrous sulphate, gr 3 tds, or reduced iron gr 1 tds, may also be used. It is essential to accustom the infant to the iron slowly, as the sudden administration of the full dose may cause colic and diarrhœa. For this reason administration is started very gradually, particularly in young infants. In bottle-fed babies the solution of iron and ammonium citrate is added to the milk, or proprietary foods containing iron are used. The mother should be warned that the stools will be dark. There are few babies whether breast fed or bottle fed who are not improved by the prescription of iron.

2 ANÆMIA OF IRON DEFICIENCY OF ADULTS

Synonyms—Idiopathic Hypochromic Anæmia; Chlorosis and Late Chlorosis

Definition—A chronic anæmia of low colour index occurring almost exclusively in women and associated frequently with glossitis and achlorhydria

Ætiology—This is the commonest of all the idiopathic anæmias, occurring typically in women between the ages of 20 and 50. The reason for its appearance in them is the loss of iron in menstruation and pregnancy, and it therefore becomes more frequent in the later years of the reproductive epoch. Moreover, women tend to eat less iron containing food than men, though they require more iron. There is a small but well defined group of cases in adolescent males, often first recognised on examination for military service, these are presumably boys who have outgrown their intake of iron. The rôle of achlorhydria in producing deficiency of iron is still disputed but it is undoubtedly less important than was at one time assumed. It is now generally believed that when achlorhydria occurs in the anæmia of iron deficiency it is the result rather than the cause of the disease, though no doubt a vicious circle develops in which anæmia predisposes to achlorhydria and achlorhydria to anæmia. The various epithelial lesions such as koilonychia, glossitis and atrophic gastritis can thus all be regarded as the effects of deficiency of iron, though achlorhydria differs from the others in being more frequently irreversible. An important group of cases is the sequel of partial gastrectomy and similar operations on the stomach. Here again, the important factors are not the neutralisation of the gastric secretion but the impaired appetite, the by passing of the duodenum and the hurry of the meal through the jejunum, iron is best absorbed in the duodenum and upper jejunum.

Pathology—The bone marrow is moderately hyperplastic, and microscopic examination shows an increased number of normoblasts and a decreased number of cells reacting to stains for iron. The spleen is moderately enlarged by a simple hyperplasia. The epithelium of the tongue and pharynx may show a leucoplakial degeneration. In patients with achlorhydria there is a diffuse chronic gastritis which eventually leads to atrophy of the mucous membrane of the stomach. The other organs exhibit the effects of a simple anæmia.

Symptoms—Symptoms may first be complained of after a pregnancy, or an influenzal attack, but careful enquiry often elicits the information that the patients were always pale, or that they have previously come under medical care for anæmia. Symptoms fall into two categories. First there are those due to anæmia—general weakness, headaches, palpitation and dyspnoea, præcordial pain on exertion is common and may be of anginal severity, slight œdema of the ankles occurs but anasarca or ascites is unusual. The second category of symptoms is composed of those due to dyspepsia, probably the result of gastritis—lack of appetite, epigastric pain and distress, retching and vomiting after meals, flatulence and bilious attacks, constipation is frequent, but diarrhoea is unusual.

The facies is often pathognomonic—the sallow, wrinkled face and prematurely grey hair contrasting with the smooth, white and transparent body skin. The nails are frequently brittle and painful and occasionally they are hollow and depressed like a spoon (koilonychia). On cure of the anæmia the new nail exhibits the normal contour and consistence. Glossitis is present in about half the cases. It is often painless and unknown to the patient, but, on the other hand, it may be the chief complaint. In the active stages the tongue is reddened and excoriated, and vesicles may appear and break down to form shallow ulcers. In the chronic and quiescent stages the filiform papillæ are destroyed, leaving a smooth bald tongue. The inflammation may spread to the buccal mucosa and to the corners of the mouth, the condition known as angular stomatitis. Passing backwards to the pharynx, it produces huskiness and a most troublesome dysphagia, which may be the presenting symptom (the Plummer Vinson syndrome, see p 542). The spleen is palpable in less than

10 per cent of cases of idiopathic hypochromic anæmia and is rarely greatly enlarged. The other signs are those of anæmia. There are no changes in the spinal cord, but functional nervous disorders, nervous breakdowns, aphonia and pruritus frequently occur. The menses are often scanty by the time the anæmia has developed but they may be heavy after treatment with iron or in women nearing the menopause.

In about 50 per cent of cases there is achlorhydria after stimulation with histamine but in contrast to pernicious anæmia Castle's intrinsic factor is preserved. Achlorhydria is more common in the later age groups and it can be attributed to an acceleration by iron deficiency of the normal increase of achlorhydria with age. It usually persists when the anæmia is cured but free hydrochloric acid may return. The colour index is low, and the red cells are usually smaller than normal. It is essentially a hæmoglobin deficiency, and often the red cell count is little below normal. The white cells and platelets are normal, an occasional normoblast may be present. Reticulocytes are within normal limits, and van den Bergh's reaction is negative. The serum iron is low. A typical count is red cells, 3,500,000 per c mm, hæmoglobin, 5 g (35 per cent), colour index, 0.5, white cells, 7000, differential count, normal. On treatment with iron there is a reticulocyte crisis, most marked in the most anæmic cases, but seldom exceeding 15 per cent., the red cells are rapidly restored to the normal number, and the hæmoglobin is more slowly regenerated. There may be a transient erythrocytosis during the recovery phase.

Complications and Sequelæ—The Plummer-Vinson syndrome is the most important complication, occurring in about 15 per cent of cases. The changes in the epithelium of the tongue and pharynx predispose to malignant disease, and epithelioma of the tongue and carcinoma of the hypopharynx develop in a few instances. There is a risk of transition into pernicious anæmia, most marked in women with a family history of that disease, but in my experience the risk is not great. Indeed, if an iron deficiency anæmia gives place to a megaloblastic anæmia, the first thing to suspect is steatorrhœa.

Diagnosis—Care should be taken to exclude other causes of anæmia, more especially malignant disease, and it is wise to remember that idiopathic hypochromic anæmia is uncommon in males and in females past the menopause. The pallor is sometimes mistaken for that of myxœdema, and indeed it is a common mistake to diagnose myxœdema when it is not present and miss it when it is.

The symptoms may suggest pernicious anæmia but the blood picture and marrow findings are quite distinctive. If the spleen is enlarged the differentiation from splenic anæmia may present some difficulty. In splenic anæmia the enlargement of the spleen is greater, there is often a history of jaundice or hæmatemesis and there may be signs of liver damage or portal hypertension. In the absence of such symptoms the patient should first be treated with large doses of iron, when both the anæmia and the splenic enlargement will disappear if the correct diagnosis is idiopathic hypochromic anæmia.

Course and Prognosis—The disease is chronic, and the average duration of symptoms before treatment is 5 years. It is rarely fatal, but in the absence of proper treatment many patients remain invalids for years. There is a strong tendency to relapse, which can only be avoided by re-examination at intervals or by persisting with a small dose of iron.

Treatment—The patient should be encouraged to take a well balanced diet, with adequate protein and vitamins. Medical treatment is by large doses of iron by mouth, either ferrous sulphate in tablets of gr 3, t.d.s., p.c., or a mixture containing iron and ammonium citrate, gr 20 t.d.s., p.c. In cases which are resistant to treatment these doses can safely be doubled. If there is intolerance, other preparations such as ferrous gluconate or colloidal ferric hydroxide may be tried. Tablets are convenient but fluid preparations are sometimes more efficacious. Liver, stomach, folic acid and cyanocobalamin are of no value in iron deficiency and blunderbuss preparations containing iron plus these substances are to be condemned. Iron can be

given intravenously, the usual preparation for this purpose being the saccharated oxide of iron. With this it is possible to rise by graded steps from an initial dose of 25 to 50 mg Fe a day to a maximum dose of 100 to 200 mg Fe a day intravenously and so to satisfy within a week or 10 days the calculated deficit in circulating hæmoglobin and stores of iron. As is true of all forms of intravenous therapy, intravenous iron is not entirely free from danger and the following comments may be made. If iron is not effective by mouth, it is unlikely to be effective parenterally, the only important exception to this rule is steatorrhœa. Most iron salts are highly toxic on parenteral administration and only preparations which have been specifically manufactured and tested for intravenous injection should be used. Apart from failure of absorption in steatorrhœa, the chief use of intravenous iron is in patients who cannot tolerate iron by mouth, such intolerance is most commonly observed in anæmia after gastro-intestinal operations. Transfusion should seldom be necessary in the anæmia of iron deficiency. In younger subjects menorrhagia may be relieved by rest at the periods, but after 40 it is usually more intractable, and if it persists then, it is advisable to induce an artificial menopause by means of operation or irradiation. If dysphagia is troublesome, it is probably best treated by dilatation of the stenosed area in the hypopharynx or upper œsophagus under direct vision through an œsophagoscope.

3. PERNICIOUS ANÆMIA

Synonym — Addison's Anæmia

Definition — A disease characterised by atrophy of the mucosa of the body of the stomach, megaloblastic anæmia and a tendency to degeneration of the spinal cord which pursues a remittent course, and which is invariably fatal unless appropriate treatment is instituted.

Ætiology — The disease is most common between the ages of 40 and 60, though analysis shows that it becomes relatively more frequent in each decade. It is very rare before the third decade, and the diagnosis should not be accepted in a child or young adult until other causes of megaloblastic anæmia have been excluded. It is a disease of the white races and is rarely seen in people of pure Asian or African stock. There is a hereditary proclivity, which probably depends on an inherited predisposition to atrophy of the gastric mucosa. Not only pernicious anæmia but also achlorhydria is believed to occur more commonly than normal in the relatives of those affected by the disease. Recent statistics suggest that pernicious anæmia is more common in women than men.

Megaloblastic degeneration of the bone marrow was the first feature emphasised by students of pernicious anæmia. Later it was learned that this was common to a group of related anæmias of which pernicious anæmia is only one member. The distinctive lesion of pernicious anæmia which no treatment removes is atrophy of the secreting epithelium of the body of the stomach and achylia is a cardinal symptom. This atrophy is apparently not secondary to inflammation and it is therefore different from the chronic atrophic gastritis which is found in other forms of achlorhydria and in the anæmia of iron deficiency. It is usually an age change in those with the hereditary predisposition but it appears sometimes to result from endocrine disturbances such as hyperthyroidism, myxœdema and pituitary insufficiency. It is accompanied by a failure on the part of the stomach to secrete a ferment like substance described by Castle as the *intrinsic factor*. Intrinsic factor is necessary for the absorption of cyanocobalamin which is the *extrinsic factor*. In the absence of cyanocobalamin the bone marrow undergoes megaloblastic degeneration and degenerative changes occur in the spinal cord and peripheral nerves. A deficiency disease of this kind is known as a *conditioned deficiency*. In pernicious anæmia it can be demonstrated by suitable techniques that there is no intrinsic factor in the gastric juice, that cyanocobalamin is not absorbed from the intestine and that the level of cyanocobalamin in

the plasma is much below normal. An apparent objection to explaining pernicious anæmia in terms of loss of intrinsic factor is the fact that patients do not always develop pernicious anæmia after total gastrectomy. The reason for this is probably that the body normally has large stores of cyanocobalamin and after total gastrectomy the patient may not live long enough for these stores to be exhausted.

When folic acid was isolated, it was discovered that all the megaloblastic anæmias respond to it. Although pernicious anæmia responds to folic acid, the repair of the anæmia is not so satisfactory as with cyanocobalamin; the spinal lesions are not improved and may indeed be aggravated. It would appear that cyanocobalamin takes part in the chain of processes concerned in the manufacture of blood cells, and here it can to a large extent be replaced by folic acid. On the other hand, megaloblastic anæmias which are due to deficiency of folic acid cannot be cured with cyanocobalamin. This suggests that folic acid tests at a later stage of the manufacturing process than cyanocobalamin. Cyanocobalamin is also necessary for the nutrition of the long neurones of the postero-lateral columns of the spinal cord and here it cannot be replaced by folic acid. The megaloblastic anæmias can be arranged in a spectrum according to their response to cyanocobalamin and folic acid.

- (a) *Addisonian pernicious anæmia*.—A pure deficiency of cyanocobalamin due to absence of intrinsic factor.
- (b) *Fish tapeworm anæmia*.—A pernicious type of anæmia may be associated with infestation by *Diphyllobothrium latum*. Apparently the worm diverts cyanocobalamin from the host. Subacute combined degeneration may occur.
- (c) *Intestinal stenosis and intestinal anastomosis*.—Megaloblastic anæmia may occur when there is stenosis or stagnat loops of small intestine. In these conditions the absorption of both cyanocobalamin and folic acid may be affected.
- (d) *Steatorrhœa*.—Megaloblastic anæmia is almost the rule in sprue (p. 623) and a similar anæmia may occur in other conditions in which the absorption of fat is impaired, such as coeliac disease, idiopathic steatorrhœa, pancreatic disease and gastro-colic fistula. The defect is usually in the absorption of folic acid.
- (e) *Nutritional macrocytic anæmia*.—This condition is rare outside the tropics and is therefore considered on p. 475. Not all these anæmias are megaloblastic. When they are, they are usually due to deficiency of folic acid, though a primary deficiency of cyanocobalamin has been seen in vegetarians who have eschewed eggs and dairy products.
- (f) *Megaloblastic anæmia of infancy*.—A rare condition seen only in artificially-fed babies and due to lack of folic acid.
- (g) *Pernicious anæmia of pregnancy*.—See p. 749.

Megaloblastic anæmia has been ascribed to cirrhosis of the liver, but this is probably the coincidence of cirrhosis with pernicious anæmia or nutritional anæmia. A few cases of unexplained megaloblastic anæmia have been described under the headings of achrestic, idiopathic or refractory megaloblastic anæmia; such cases are extremely rare, and the majority of patients diagnosed as having pernicious anæmia with normal gastric secretion are really suffering from unrecognised steatorrhœa.

Pathology.—The remainder of this section deals with Addisonian pernicious anæmia. Few patients now die of untreated pernicious anæmia. In such cases the main changes seen at necropsy are anæmia, deposition of iron in the tissues, and megaloblastic hyperplasia of the bone-marrow. To demonstrate the changes in the stomach, the tissues must be fixed immediately after death.

Symptoms.—Patients with pernicious anæmia are not infrequently well built, with broad facies, short deep chests and wide sub-costal angles; the hair is often prematurely grey, and the skin may be pigmented. Symptoms fall into three main

categories according as they are due to changes in the blood, the alimentary tract or the nervous system. The anæmia may be profound by the time the patient presents himself for treatment and the red cell count may even fall below 1 million. Dyspnoea, weakness, palpitations and signs of heart failure appear. A lemon yellow colour of the skin was common in the days before liver therapy was introduced but now that patients come under effective treatment early it is not often seen. The same is true of splenomegaly which requires considerable time for its development and is now found in only about 5 per cent of untreated patients. The temperature may be slightly raised. Angina may occur from impoverishment of the blood supplied to the heart, and intermittent claudication from similar effects in the limbs. The liver may be enlarged. The urine contains much urobilin and often a trace of albumin. Alimentary symptoms constitute an important chapter of the disease. Glossitis of the type described in idiopathic hypochromic anæmia occurs in over 50 per cent. of cases, but curiously enough there is no tendency to involvement of the pharynx, or to dysphagia. It may precede the anæmia by some years. Achlorhydria is an invariable symptom and pepsin is greatly reduced or absent. Achlorhydria has many times been demonstrated before the onset of the anæmia, and it persists when the blood has been repaired. Dyspepsia is frequently present, with flatulence, ill defined generalised abdominal pain, soft bowel movements and recurrent attacks of diarrhoea. The dyspepsia is partly due to the achlorhydria but it is greatly aggravated by the anæmia if it persists after repair of the anæmia, carcinoma of the stomach or disease of the gall bladder should be suspected. Nervous symptoms due to subacute combined degeneration of the spinal cord are an integral part of the disease but for convenience they are described elsewhere (p 1550). Mental symptoms appear in a small percentage of cases, they are usually delusions of persecution and the patient swears that he is being poisoned by his relatives or his physician. Exceptionally such patients become stuporose and die in coma even though their anæmia is not profound.

The cardinal feature of the blood picture is megalocytosis. By the time the patient seeks medical advice the red cells are often less than 2 millions per c.mm. and counts of the order of half a million have occasionally been obtained. Haemoglobin is not reduced to the same extent as the red corpuscles and the colour index is above unity. The mean diameter of the red cells averages about 8.3 microns there is much anisocytosis and poikilocytosis. Reticulocytes are within normal limits except during a remission, spontaneous or induced. Normoblasts and megaloblasts are often present, more especially in the agonal stages of the disease and also on the inception of very active treatment, they are rarely present in the peripheral blood in mild cases. The serum is brownish yellow and the indirect van den Bergh reaction is positive. The white cells are reduced in number an average count being about 4 000, the decrease is chiefly due to diminution in the granulocytes and the monocytes. The neutrophil cells are of an old type, many having 5 or more lobes to their nucleus and occasional giant neutrophils and myelocytes are present. Platelets are scanty. The marrow smear shows megaloblastic hyperplasia.

Remissions and relapses were one of the most constant features of the untreated disease which was nevertheless usually fatal in 1 to 3 years. The cause of the remissions is uncertain but they are possibly related to phasic changes in the bacterial flora of the intestine which affect the absorption of cyanocobalamin and folic acid.

Complications and Sequelæ—Since effective treatment was introduced complications have become infrequent. The incidence of subacute combined degeneration has fallen to about 10 per cent. Retinal hæmorrhages may be seen in patients who are severely anæmic apart from this purpura and hæmorrhage are unusual, though they undoubtedly occur on occasion. Gout and venous thrombosis occasionally occur during initial treatment. Patients with pernicious anæmia have about three times the normal liability to carcinoma of the stomach. This risk should never

theless be kept in its proper perspective, for as Jennings has shown, it means that whereas the annual chance of a man in his fifties developing cancer of the stomach is 1 in 1000, in pernicious anæmia it is 1 in 300. It is a curious fact that the cancer does not usually develop in the fundus and body of the stomach, where the pathological changes of pernicious anæmia are localised, but more commonly in the pyloric region.

Diagnosis.—The disease is often suggested by the triad of symptoms glossitis, anæmia and acroparesthesia in a patient in the appropriate age group, and it is confirmed by the blood picture. It is, nevertheless, not uncommonly missed in the elderly, the parchment skin and the general enfeeblement being regarded as the inevitable concomitants of age. Such mistakes can be avoided by thinking of the possibility of anæmia and testing the hæmoglobin. In cases of doubt two questions should be answered. The first is whether the anæmia is megaloblastic, this can be decided by marrow puncture. The second is whether it is Addisonian pernicious anæmia. In true pernicious anæmia the test meal reveals achlorhydria, and other causes of megaloblastic anæmia such as steatorrhœa are absent. In making the initial diagnosis it is wise to have a barium meal to exclude gross alimentary disease in general, and cancer of the stomach in particular. Aplastic anæmia may be mistaken for pernicious anæmia, but treatment with cyanocobalamin is unsuccessful and the marrow is found to be aplastic. Aleukæmic leukaemia and chronic hæmolytic anæmia can likewise be differentiated by careful analysis of the symptoms, the blood picture, and the marrow smear. In the absence of severe complications anæmia which does not respond to cyanocobalamin in effective dosage is almost certainly not pernicious anæmia.

Prognosis.—The gastric lesion appears to be incurable, but with adequate and regular treatment the anæmia is cured, spinal symptoms completely arrested and the patients live out the normal span in full health.

Treatment.—As the treatment of pernicious anæmia is a form of substitution therapy which must be continued for the rest of the patient's life, it should never be embarked on without confirmation of the diagnosis. In cases of doubt this means marrow puncture and test meal. If doubt still remains, the patient should be referred to an expert hæmatologist. Preparations containing a farrago of iron, liver, stomach, vitamins, etc., should never be employed, for in the very rare cases in which more than one hæmaturic principle is required, they should be added *seriatim* and in adequate dosage so that the effects of each can be assessed. On instituting successful treatment in a patient with pernicious anæmia there is a reticulocyte crisis, which reaches its maximum between the tenth and fourteenth days with oral therapy, and between the third and the seventh days with parenteral therapy. The peak is directly proportional to the severity of the anæmia, and values of 30 to 40 per cent are by no means uncommon. The blood and the general condition of the patient are gradually restored to normal, glossitis becomes quiescent and the surface of the tongue may be reclothed with filiform papillæ. The nervous symptoms improve more slowly, and gross spastic paralysis is unlikely to be repaired.

The modern treatment of pernicious anæmia can almost be summed up in the word cyanocobalamin. A dose of 100 microgrammes is injected intramuscularly weekly until the red cell count is normal and the maximum clinical remission has been obtained. Double this dosage should be given if there are neurological complications. For maintenance treatment a dose of 50 microgrammes is injected once a fortnight, in neurological cases the maintenance dose should be 100 microgrammes once a week for as long as improvement seems able to occur, i.e. from 6 months to 2 years. Better effects are obtained with small doses frequently than with large doses at longer intervals but many patients remain well with doses of the order of 50 microgrammes every 3 weeks or 100 microgrammes every month. Two innovations have recently been suggested in the use of cyanocobalamin. Mollin and Ross state that a much higher initial dosage should be used to replenish the body stores. They advise 5 injections

of 1000 microgrammes in the first week or two of treatment, followed by a maintenance dose of 50 microgrammes fortnightly, or 100 microgrammes monthly. Although intrinsic factor has not yet been isolated in a pure form, a number of commercial firms have prepared tablets containing cyanocobalamin, plus a concentrate of intrinsic factor for administration by mouth. This, of course, is merely a refinement of the original treatment with desiccated stomach. Oral treatment is more expensive than cyanocobalamin by injection, and it places a greater strain on the patient's co-operation. It should therefore only be employed when treatment by injection cannot conveniently be arranged.

Cyanocobalamin appears likely to replace all forms of liver in the treatment of pernicious anaemia. The use of folic acid is contraindicated. Hydrochloric acid is rarely necessary, for if dyspepsia persists after repair of the anaemia some cause other than achlorhydria should be suspected. Sometimes while the red cell count is rising or during maintenance treatment the patient may develop a hypochromic anaemia requiring iron therapy. Apart from patients in the initial phase of treatment and women who are still menstruating, iron deficiency is rare in pernicious anaemia and it should always suggest steatorrhoea or a complication such as carcinoma.

The action of cyanocobalamin is prompt and regeneration of the bone marrow is apparent within a couple of hours of injection. Transfusion is therefore hardly ever required and it should be withheld if at all possible, in view of the danger of precipitating acute heart failure in patients who are profoundly anaemic. In a patient with an initial red cell count of 1 million, the count will rise to 3 million in 2 to 3 weeks. The degree of activity should be determined by the patient's feelings. Pernicious anaemia occurs in elderly people who do not tolerate strict confinement to bed well and if there are no signs of heart failure, there is no point in keeping them there. A full mixed diet is allowed. There is often a tendency to put on weight excessive in remission and this should be avoided. Regular blood examinations should be carried out at least once every 3 months. If the patient fails to get back to a normal count or if a patient who is doing well relapses while on the same maintenance dose, a complication such as hypothyroidism or carcinoma should be suspected. In the absence of indications of this kind repeated radiographic examinations of the stomach are not necessary. In general, few things in medicine are as satisfactory as the treatment of pernicious anaemia, and patients should be expected to live a life of full activity.

APLASTIC ANÆMIA

Synonyms—Aregenerative Anaemia, Refractory Anaemia, Panmyelopathy.

Definition—Aplastic anaemia is produced by aplasia of the bone marrow which results in reduction or total failure of blood regeneration. Usually all three elements in the bone marrow—erythropoietic tissue, leucopoietic tissue and megakaryocytes—are simultaneously involved. Rare cases occur in which there is a pure lesion of one of these tissues, and not infrequently one of them is predominantly affected. The term *aplastic anaemia* is applied more particularly to cases in which the erythropoietic tissue is especially damaged.

Ætiology—The disease occurs at all ages and in both sexes. In a number of cases the aplasia of the bone marrow is due to destruction by a well recognised poison. The list includes benzol and many of its derivatives, such as arseno benzol, dinitrophenol, trinitrotoluene, chloramphenicol and the sulphonamides, mepacrine hydrochloride and gold. Roentgen rays and radioactive substances are important causes, the latter being most dangerous when they are taken into the body and produce persistent radiation. In a large proportion of cases no noxious agency can be traced and it is possible that many are due to an idiosyncrasy to substances not normally regarded as harmful, a phenomenon we have already learnt to recognise in amido

pyrine agranulocytosis and Sedormid purpura. On rare occasions more than one member of a family has been affected. In familial cases in childhood, hypogonadism and developmental abnormalities, particularly of the bands and kidneys, may also be present (Fanconi's syndrome).

Pathology.—In the classical aplastic anæmia the marrow may be hypocellular or acellular or there may be replacement by fibrous tissue. An actual excess of erythropoietic tissue may be found in radium poisoning, presumably from an arrest in the maturation of the cells. A similar maturation arrest has been described in other cases which behaved like aplastic anæmia during life, though in my experience this is unusual. Necrotic ulcers may be found in the mouth and bowel. The liver, spleen and lymph glands show no gross change, but microscopically there is usually some hæmosiderosis of the liver and spleen, attributable both to the absorption of extravasated blood and to the breakdown of transfused red cells.

Symptoms.—Aplastic anæmia is not common, having probably only one quarter the frequency of pernicious anæmia. The onset is commonly insidious, and there may be several months of increasing fatigability before the patient is finally pulled up by the severity of the anæmia, or by an acute crisis such as hæmorrhage or infection. Purpura, bleeding from the nose and gums, or infection of an agranulocytic type may be the first complaint. Spontaneous remissions of the symptoms occur occasionally, but they are rarely complete or of long duration. There are no specific alimentary or nervous symptoms. Physical examination is commonly negative except for the anæmia and such complications as purpura and agranulocytosis. The spleen is only rarely palpable and the lymph glands and the liver are not enlarged. The blood picture is characterised by a decrease of all the cells, erythrocytes, leucocytes and platelets, the absence of immature white cells and nucleated red cells, and the lack of signs of reaction, such as hypochromia, anisocytosis and reticulocytosis. By the time a blood count is done the red cells have often fallen to 1.5 million per c.mm. and the colour index is above unity. Van den Bergh's reaction is negative. The white cells are about 3000 or 4000 per c.mm., usually fallen below 2000 before death, the diminution is chiefly due to the small number of polymorphonuclear cells. In chronic cases a very considerable degree of macrocytosis may develop, and so long as the colour index remains high and the leucocyte count low, the disease cannot be regarded as cured.

Diagnosis.—At the onset the illness is often confused with one of the megalo-blastic anæmias, but it can be differentiated by sternal puncture and the failure to respond to cyanocobalamin or folic acid. Essential thrombocytopenia may be suggested by the low platelet count and the hæmorrhagic tendency, but is excluded by the leucopenia and the non regenerative character of the anæmia. Aleukæmic leukaemia offers the most difficulty. The absence of enlargement of the lymph glands, liver or spleen, however, should differentiate aplastic anæmia from this disease. In doubtful cases a sternal marrow puncture or biopsy should be performed.

Prognosis.—In a series of cases observed during the last decade, 30 per cent. died within 1 year and 60 per cent. within 2 years of coming under treatment, a few survived for 5 to 10 years but none longer than this. Complete recovery may occur, but probably in not more than 5 per cent. of cases. Patients with thrombocytopenia and a hæmorrhagic tendency do badly. However well the patient appears clinically, the prognosis should always be guarded as long as the blood picture is abnormal for such patients are always liable to sudden deterioration from infection or an acute hæmolytic reaction.

Treatment.—In all cases enquiry should be made of exposure to toxic substances and further contact prevented. Anæmia is combatted by transfusion, and infection by penicillin, unfortunately there is no remedy for the thrombocytopenia. Iron, liver and similar remedies are of little value, but it is reasonable to try the effects of cyanocobalamin and folic acid if there is any doubt about the diagnosis. The

blood should be brought approximately to normal by a rapid series of transfusions, or by a continuous transfusion of 2 or 3 litres of blood. If it is then possible to maintain a normal count by transfusions at intervals of 2 or 3 weeks, there is some hope that the bone-marrow may gradually regain its hæmopoietic function. It is undesirable to allow the hæmoglobin to remain below 50 per cent. for long periods, as there is a risk of heart failure, and it is better and more convenient to give small transfusions at frequent intervals, *i.e.* 1 or 2 pints of blood a fortnight.

HÆMOLYTIC ANÆMIA

In discussing the symptomatic anæmias, I have mentioned the occasional development of anæmia from hæmolysis of the corpuscles by micro-organisms, bacterial toxins and other poisons. There is also evidence that excessive hæmolysis plays a part in the pathology of the megalocytic anæmias due to deficiency of hæmopoietic principles. There now remains for discussion a group of hæmolytic anæmias which are relatively uncommon and of which the most important examples are due to congenital anomalies in the red blood cells. Before treating these diseases individually, it will be convenient to describe the characteristics which are common to all the hæmolytic anæmias. If a great many red cells are broken down in a short time, there is hæmoglobinuria and jaundice, but in chronic hæmolytic anæmia it is sometimes surprising how slight is the jaundice. The colour index varies according to the mode of reaction of the bone-marrow, but it is usually round about unity and there may be frank macrocytosis. Owing to the vigorous attempts of the bone-marrow to repair the anæmia, the reticulocyte count is high, and nucleated red cells may appear in the peripheral blood. In chronic hæmolytic anæmia the white cells are unaffected or a little diminished. When hæmolysis is acute and rapid, there is a leucocytosis, during which immature white cells may appear in the peripheral blood; the platelets first fall and later rise above their normal level. Apart from the hæmolysis, which gives rise to anæmia, enlargement of the liver, spleen and occasionally the lymph glands, hyperplasia of the bone-marrow and hæmosiderosis, there are no signs of systemic disease and the alimentary and nervous systems are normal.

THE HEREDITARY HÆMOLYTIC ANÆMIAS

Hæmolytic anæmias can be classified as hereditary and acquired; the hereditary are due to an intracorpuseular defect, and the acquired to an extracorpuseular defect. When there is an intracorpuseular defect the Coombs test (p. 744) is usually negative and normal blood transfused into the patient is not hæmolyzed and survives the normal time. Four inherited anomalies in the shape of the red cell are known: 1. *elliptocytosis* (syn. ovalocytosis) the red cells are biconvex; this is a relatively harmless abnormality and will not be further discussed. In *spherocytosis* they are thicker than normal. In *drepanocytosis* many of the red cells become sickle-shaped when they are deprived of oxygen. In *leptocytosis*, which is seen in Mediterranean anæmia, they are abnormally thin. The abnormalities in shape are probably secondary abnormalities in the hæmoglobin. At the time of writing, in addition to normal adult hæmoglobin (hæmoglobin A) and fetal hæmoglobin (hæmoglobin F) there have been described sickle-cell hæmoglobin (hæmoglobin S), hæmoglobin C and hæmoglobin I. In acholuric jaundice the spherocytes are more liable to destruction by the spleen than normal red cells, and the anæmia is relieved by splenectomy. Splenectomy is not effective in the other hereditary hæmolytic anæmias, and cortisone is of no value. These four anomalies of the red cell are apparently inherited as Mendelian dominants. In sickle-cell disease and in Mediterranean anæmia there are mild and severe forms of the disease. These are distinguished respectively as sickle-cell trait and

sickle-cell disease, and thalassæmia minor and major. The hypothesis has been advanced that the mild disease occurs in people who are heterozygous for the affected gene, and the severe in the homozygous. This theory was supported by the discovery that in sickle-cell anæmia nearly all the hæmoglobin in the red cells is abnormal (hæmoglobin S), whereas in the sickle-cell trait 40 per cent. is abnormal and 60 per cent. normal. However, it did not explain the widely different relative incidence of anæmia and trait in different parts of the world. Subsequently another abnormal hæmoglobin (C) was discovered, and it was shown that sickle-cell anæmia might be caused not only by two genes for hæmoglobin S, but one gene for hæmoglobin S and one for hæmoglobin C, or one for hæmoglobin S and one for thalassæmia. The further unravelling of these problems is now primarily of ethnological and genetic interest. It is believed that most cases of acholuric jaundice are heterozygous for the affected gene, and the reason for the variations in intensity of the disease are not known. Cases of hereditary hæmolytic anæmia which are normocytic have been described; they are rare. For convenience, hæmolytic anæmia with nocturnal hæmoglobinuria is included in this section, as it is due to an intracorpuseular defect.

HEREDITARY SPHEROCYTOSIS.

ACHOLURIC JAUNDICE

Synonyms.—Hereditary Spherocytosis; Hæmolytic Anæmia (type Chauffard-Minkowski).

Definition.—A hereditary disease, which is characterised by increased fragility of the red blood cells, a variable degree of jaundice and anæmia, splenomegaly and a strong tendency to the formation of gall-stones.

Ætiology.—The red blood cells are more spherical than normal and therefore less resistant to swelling when exposed to hypotonic saline. In the body they are presumably less viable than normal and more rapidly destroyed by the spleen. The abnormality of the corpuscles is transmitted as a Mendelian dominant and affects chiefly people of European stock. It exists from birth, but though the symptoms of the disease may be present from early infancy, they may not manifest themselves until a much later date, and may even remain in abeyance throughout life. There are no abnormal hæmolysins in the blood, nor is there any evidence that the hæmolysis is dependent on a primary fault in the spleen.

Pathology.—The bone-marrow shows an extreme degree of hyperplasia of the normoblastic type. The spleen usually weighs from 1 to 3 lb. and the pulp is congested with red blood cells.

Symptoms.—The severity of the disease is extremely variable. There may be no symptoms at any time, the condition being recognised only on a routine examination of the blood. Most patients have a mild degree of jaundice, and give a history either that they have always been jaundiced, or that they have always been liable to attacks of jaundice. There is no pruritus. The anæmia is usually mild but it is more severe in cases presenting in early life. It is characteristically marked by periodic exacerbations. These are usually due to increased hæmolysis, and are accompanied by an exaggeration of the reticulocytosis and jaundice. Occasionally, however, more severe crises occur in which jaundice and reticulocytosis disappear, the patient becomes profoundly anæmic, and the marrow is found to be temporarily aplastic. Crises of this second type may affect several members of a family at the same time and they are probably provoked by intercurrent infection.

Calcium bilirubinate gall-stones may develop as a result of the chronic bilirubinæmia. These may give rise to attacks of biliary colic, which may be accompanied by an increase in the jaundice, which is quite independent of the hæmolytic crises. An unexplained complication is chronic ulceration of the legs, which may be the chief and sometimes the only symptom of the disease.

Splenomegaly is usually present; though occasionally extreme, it is common of moderate degree. The spleen may increase in size during a crisis, and may be painful and tender.

The *fæces* are normal in colour, and the urine, though dark as the result of the presence of urobilin, contains no bile.

In normal fully oxygenated blood, the red corpuscles show no hæmolytic solution in a 0.50 per cent. solution and only slight hæmolytic solution in a 0.45 per cent. solution of sodium chloride. In acholuric jaundice the fully oxygenated corpuscles show gross hæmolytic solution in a 0.45 per cent. solution and lesser degrees of hæmolytic solution in stronger solutions sometimes even as high as a 0.80 or 0.85 per cent. solution. The corpuscular diameter is usually diminished and often very markedly so, but occasionally it is normal. The corpuscles are disproportionately thick, so that the corpuscular volume and colour index instead of being diminished are normal or above normal. This discrepancy between corpuscular volume and colour index on the one hand, and corpuscular diameter on the other, occurs in no other disease, and immediately distinguishes acholuric jaundice from pernicious anaemia. In stained films there is gross irregularity in the size of the corpuscles; the small ones tend to be deeply stained, while the large ones are feebly stained and often polychromatic. In shape they are of a remarkably uniform roundness, and stippled corpuscles are unusually scarce. The anaemia is usually only moderate in degree, red cell counts between 3 and 4 million per c.m. being most common, and the white cells are normal. Reticulocytes frequently constitute over 10 per cent. of the red corpuscles and are sometimes much more numerous. In hæmolytic crises large numbers of normoblasts may appear in the peripheral blood and there is often a polymorphonuclear leucocytosis. There is no evidence that hæmoglobinuria ever occurs in acholuric jaundice of the familial type. As the jaundice is hæmolytic the van den Bergh test gives only an indirect reaction. Occasionally, however, obstructive jaundice is present as well owing to the presence of a pigment stone in the common bile duct; a direct reaction is then present as well.

Diagnosis.—The diagnosis is suggested by the association of splenomegaly with long-standing jaundice or recurrent attacks of jaundice. It is strengthened by the history of jaundice in other members of the family. Its confirmation depends on finding increased fragility of the red corpuscles and the characteristic blood picture, particularly the discrepancy between the corpuscular volume and diameter. The blood picture distinguishes the condition from other hæmolytic anaemias, from pernicious anaemia, chronic myelogenous leukaemia, and splenic anaemia. Chronic ulceration of the legs should always call to mind the possibility that the underlying cause may be acholuric jaundice, even in the absence of jaundice and splenomegaly. Finally, it must be remembered that attacks of biliary colic may occasionally be a complication of acholuric jaundice.

Prognosis.—The earlier in life the onset, the more serious the disease, and in infancy and childhood death may occur from anaemia, or growth may be retarded. In adults the anaemia is usually mild but the biliary complications may be dangerous. Splenectomy is almost uniformly curative and the mortality of the operation is low.

Treatment.—In latent cases no treatment may be required but in view of the risk of gall-stones and anæmic crises and the safety of operation, splenectomy should be advised if there are any symptoms. At the same time cholecystectomy may be performed if gall-stones are present. In very severe crises transfusion may be necessary to prepare the patient for operation. The effects of splenectomy are dramatic: the jaundice and the anaemia quickly disappear and the leg ulceration heals. The increased fragility persists, though it may be slightly lessened. The disproportionate thickness of the corpuscles and the resulting discrepancy between the corpuscular volume and the diameter remain, but the reticulocytosis and leucocytosis, which are secondary to the anaemia, usually disappear.

② SICKLE-CELLED ANÆMIA

Synonym.—Hereditary Drepanocytosis.

Definition.—A severe anæmia, characterised by the appearance in the blood of a number of red blood corpuscles of a peculiar sickle shape.

Ætiology and Pathology.—In the sickle-cell anomaly, the blood may be relatively or completely normal when freshly drawn, but when a drop of blood is sealed under a coverslip on a slide and allowed to stand, a number of the corpuscles become elongated and sickle-shaped. The phenomenon depends on reduction of the oxygen tension and can easily be accelerated by simple physical or chemical procedures. The sickle cells do not aggregate and sediment as readily as normal cells and there is a considerable difference in the sedimentation rate of reduced and aerated blood. The sickle-cell anomaly is practically confined to the negro race, being found in about 20 per cent. of some West African tribes and in over 7 per cent. of American negroes. In the U.S.A. about 1 in 50 with the trait have anæmia, but in Africa the ratio may be less than 1 in 1000. People with the trait normally have about 1 per cent. of sickle-cells in the red cells of their venous blood, whereas in sickle-cell anæmia 30 to 60 per cent. of the red cells show sickling in the venous blood, without oxygen deprivation. The trait alone does not appear to produce any symptoms.

Symptoms.—The disease usually dates from infancy. The patients are obviously anæmic, and the sclerotics exhibit a greenish-yellow tinge. The liver is bulky, but the spleen is not enlarged. The disease is characterised by intermittent paroxysms of fever, up to 103° or 104° F., with severe stabbing pains in the muscles and joints, which last for 2 or 3 weeks. In the intervals the patients suffer but little, though they are listless and depressed. Chronic ulceration of the legs occurs in a high proportion of cases. The red blood corpuscles in the intervals reach a number of about 3,000,000 per c.mm., but during the paroxysms they rapidly fall to less than half that number. The white cells are usually about 15,000 c.mm., but may rise to as much as 40,000. The sickle-shaped corpuscles vary in numbers. They appear to increase in number on a warm slide. The coagulation-time, the bleeding-time, the fragility of the corpuscles and the numbers of platelets are all within normal limits.

Course and Prognosis.—The course of the disease is slow but progressive, and death usually occurs before the age of 30.

Treatment.—Up to the present time, no treatment has appeared materially to influence the progress of the disease, and splenectomy is of no value.

3. MEDITERRANEAN ANÆMIA

Synonyms.—Hereditary Leptocytosis ③ *Thalassæmia*; Familial Erythroblastic Anæmia of Cooley; Familial Microcytic or Hypochromic or Target-Cell Anæmia.

This is a hereditary dystrophy of the erythron in which the red cells are thinner than normal. Under the microscope some of them have an oval or target shape and others are large, pale, leaf-like structures. Although they are more resistant to hypotonic saline, they are more rapidly broken up in the body than normal. This abnormality is practically confined to persons of Mediterranean stock. In typical cases anæmia manifests itself soon after birth, and life is rarely prolonged past childhood. The anæmia is of the hæmolytic type and characterised by numerous erythroblasts in the peripheral blood, but the colour index is below unity owing to the abnormal shape of the red cells. Other characteristic symptoms are moogoloid facies, splenomegaly, and generalised bony changes due to hypertrophy of the marrow. The bone dystrophy is similar to osteitis fibrosa, but pathological fractures are not common, and symptoms come principally from the anæmia, which is severe and ultimately fatal. Radiographic examination shows widening of the medullary portion of the bones, erosion and thinning of the cortex, and a peculiar outline of the skull often compared

to hair standing on end. Until recently it was believed that Cooley's anaemia was a disease of children which was always fatal, but it has since been learned that other members of affected families may show the abnormal type of red cell without anaemia or with only very mild symptoms. Treatment is by repeated transfusions. Splenectomy and iron are ineffective, in fact, an anaemia of low colour index in a child which does not respond to iron should suggest the possibility of Mediterranean anaemia.

4 HÆMOLYTIC ANÆMIA WITH RECURRENT HÆMOGLOBINURIA

Synonyms: ^(a) Nocturnal Hæmoglobinæmia, Chronic Hæmolytic Anæmia (type Marchiafava Micheli)

A rare disease characterised by paroxysms of hæmoglobinuria, which commonly occur at night and persistent hæmolytic anaemia. It is a disease of adult life and affects both sexes. It is apparently due to an inherent abnormality in the red cells which are unduly sensitive to hæmolysis in acidified serum. The spleen is usually enlarged though not to the same degree as in acholuric jaundice. The disease is differentiated from acholuric jaundice by the normal size, shape and osmotic fragility of the red cells and the occurrence of hæmoglobinuria, and from the paroxysmal hæmoglobinuria of syphilis by the negative Wassermann reaction, absence of relation to exposure to cold and persistence of anaemia between the paroxysms. Splenectomy has little effect and the disease usually leads to death after a few years. Treatment is by transfusion which is better tolerated if washed red cells are used.

THE ACQUIRED HÆMOLYTIC ANÆMIAS

The acquired hæmolytic anaemias are all due to extrinsic factors causing a decreased red cell life span. They are sometimes divided into symptomatic and idiopathic. A more useful classification is

- (a) Due to the direct effect of chemicals, physical agents, micro organisms, animal and vegetable poisons
- (b) Due to the development of antibodies active against the patient's own red cells
- (c) Due to increased activity of the spleen or other parts of the reticulo-endothelial system

The rare Carrion's disease of the Andes is an example of the direct attack of micro-organism on the red blood cells. More often the relation of hæmolysis to infection is obscure as in the blackwater fever of malaria or the hæmolytic anaemia that occasionally follows typhoid fever. In certain people suffering from acquired hæmolytic anaemia antibodies can be demonstrated in the serum which react *in vitro* with the patient's own red cells. Antibodies which agglutinate the red cells in the cold may appear in the serum after infections such as virus pneumonia and in other conditions. In rare cases cold agglutinins are present in high titre, a moderate hæmolytic anaemia usually develops but more dramatic and troublesome is the blockage of the circulation on exposure to cold, which may lead to gangrene of the extremities, the tip of the nose and the lobes of the ear. A cold hæmoglobinuria may develop in tertiary syphilis and lead to paroxysmal hæmoglobinuria (p 1104) this hæmolysis may be demonstrated by the Donath Landsteiner reaction.

In hæmolytic disease of the newborn and idiopathic acquired hæmolytic anaemia antibodies affecting the red cells can usually be demonstrated by special technique. One method is to use specially sensitised red cells as laboratory reagents for the recognition. More convenient is the Coombs test or antihuman globulin reaction which reveals the antibody attached to the patient's red cells. Although this test is not absolutely specific for hæmolytic anaemia due to abnormal antibodies it is

great assistance in practice. In hæmolytic disease of the newborn the antibodies are usually anti-Rh, due to incompatibility between mother and fœtus. In acquired hæmolytic anæmia of adults the nature of the antibodies is more obscure, but some of them are probably antibodies to one of the normal blood group antigens, due to some perversion of the mechanism of immunity.

In all conditions in which the spleen is enlarged, the life of the red cell may be shortened, presumably by overactivity of the normal scavenging mechanism of the spleen. This may reveal itself by a non specific anæmia and by unduly short benefit from transfusions, but in some cases, particularly in lymphatic leukaemia, a frank hæmolytic picture may be present. Anæmia of this type may also appear when other parts of the reticulo-endothelial system are diseased. Examples are seen in all forms of leukaemia, Hodgkin's disease, cirrhosis of the liver and malignant affections of the hæmopoietic system. Abnormal antibodies may appear in the serum in some of these symptomatic hæmolytic anæmias.

The treatment of the various symptomatic anæmias consists in the first place in removing the cause when possible. Iron and liver are of no value and transfusion is only temporarily effective. When there is splenomegaly, splenectomy may be desirable, even though it may be only a symptomatic remedy. Cortisone and corticotrophin are often effective.

① HÆMOLYTIC DISEASE OF THE NEWBORN

Synonyms—*Erythroblastosis Fœtalis*, *Familial Icterus Gravis Neonatorum*.

Definition—A hæmolytic anæmia which occurs in the fœtus or newborn child and which is due to incompatibility between the serum of the mother and the erythrocytes of her offspring.

Ætiology.—Hæmolytic disease of the newborn results from the iso-immunisation of the mother by a red cell antigen which she lacks, but which the child has inherited from the father, and the subsequent passage through the placenta of the resulting antibody to act on the susceptible blood of the fœtus. The distribution of the blood groups is such that in 1 pregnancy in 5 the mother's serum contains an agglutinin for an antigen of the A-B O groups contained in her fœtus and in 1 pregnancy in 10 the mother is Rh negative and the fœtus Rh positive. Nevertheless, iso immunisation and hæmolysis occur in only 1 in 400 pregnancies, because ill effects are usually prevented by the impermeability of the placenta and by the presence of protective substances in the infant's plasma. Incompatibility in the ordinary blood group factors A-B O very rarely gives rise to symptoms and the majority of cases of hæmolytic disease of the newborn are due to incompatibility in the Rh factor, the mother being Rh negative and the child Rh positive. Iso immunisation to the Rh factor does not occur unless the Rh-negative individual has a transfusion of Rh positive blood or conceives a Rh-positive child, and firstborn children usually escape hæmolytic disease, because the antigenic stimulus of more than one pregnancy may be needed to produce a dangerous level of antibody.

Pathology.—The heart is hypertrophied. The liver and spleen are increased in weight and show extra medullary hæmopoiesis, bile staining and iron pigmentation. The placenta is usually enlarged and may contain hæmatomata.

Symptoms.—Various types of the disease have been described according as oedema, jaundice or anæmia predominates. In *congenital hydrops* the child is usually born prematurely at about 36 weeks, it is swollen with dropsy and is either dead or dies a few hours after birth. More commonly the child is born about the normal time but it shows signs of distress, the amniotic fluid is yellow and the vernix caseosa a golden colour. Jaundice and anæmia are usually present at birth and they rapidly deepen the child passing into a drowsy condition and dying within a few days or weeks. In a small proportion of cases the anæmia is less acute and no jaundice

develops. A hæmorrhagic tendency due to an associated hypo-prothrombinæmia is not uncommon. Examination of the blood shows an anæmia of high colour index with reticulocytosis and many nucleated red cells. Death may occur within 24 hours of birth from heart failure, or between the second and the fifth day from damage to the central nervous system. Deaths formerly occurred at a later period from anæmia, but this should not happen when transfusion is available. *Kernicterus* is the most frequent and distressing complication (see p. 1485); cirrhosis of the liver and dysplasia of the bones are less common sequelæ.

Diagnosis.—Hæmolytic disease of the newborn should be suspected whenever anæmia or jaundice occurs in the first few days of life. It is differentiated from septic infection by the absence of fever, and from syphilis and congenital obliteration of the bile ducts by the presence of a hæmolytic anæmia. The distinction from physiological jaundice may be more difficult, but if the child is anæmic or the blood film shows many erythroblasts 48 hours after birth, the jaundice is unlikely to be physiological. If the mother is Rh-negative and the child is Rh-positive, the diagnosis is practically certain and it can be confirmed by the demonstration of anti-Rh agglutinin in the mother's serum and by a positive Coombs test with the child's red cells.

Prognosis.—The mortality in cases born alive is about 50 per cent. without treatment. The prognosis is closely dependent on the degree of anæmia at birth. Infants whose cord blood contains less than 8 grammes per cent. hæmoglobin are likely to die within 24 hours of birth, and those with hæmoglobin values over 14.5 grammes per cent. are likely to recover without treatment. In spontaneous births the nearer to term the child is born, the better the prognosis.

Prophylaxis.—The Rh factor is inherited as a Mendelian dominant, and the majority of fathers of erythroblastotic children are homozygous, i.e. they can produce only Rh-positive children. Once hæmolytic disease of the newborn has resulted from a marriage, the odds are high that subsequent children will be involved and conception should be avoided. There are no means to prevent the disease during pregnancy—cortisone is ineffective—but the mother's serum should be tested for anti-Rh agglutinin, and if this is present, arrangements should be made to begin treatment immediately after birth.

Treatment.—When anti-Rh agglutinin has been detected during a pregnancy, arrangements should be made to collect a sample of the infant's cord blood at birth. This will allow an immediate Coombs test, to confirm or disprove the diagnosis, and an estimation of the hæmoglobin, to decide the treatment. If the hæmoglobin concentration in the cord blood is less than 15.5 grammes per cent., the best treatment is replacement transfusion via the umbilical vein. If the hæmoglobin is above 15.5 grammes, it is legitimate to wait 12 hours and see if jaundice develops or the blood deteriorates. Points to be noted, apart from anæmia, are the degree of reticulocytosis, erythroblastosis, and bilirubinæmia. Loss of a previous child and prematurity would sway the balance towards more active treatment. If the infant is seen for the first time after 24 hours, and the hæmoglobin in a venous sample is below 15.5 grammes, a simple transfusion should be given. If the infant is about a week old before the diagnosis is made, transfusion is only necessary if the hæmoglobin is less than 12 grammes. Transfusion is always carried out with Rh-negative blood of the same A-B-O group as the child, and the blood of neither of the parents is suitable. The father's blood, being Rh-positive, will be rapidly destroyed and the mother's blood is harmful, as it contains the hæmolysin. Induction of labour is not usually advised unless previous children have died from hæmolytic disease; it may then allow a child to be brought into the world before the anæmia has become too intense for survival. Some authorities deprecate breast feeding on the ground that the hæmolysin may be transmitted in the milk, but it probably does more good than harm in these sick children. Owing to the frequency of hypoprotrombinæmia, vitamin K should be administered as for the hæmorrhagic disease of the newborn.

② IDIOPATHIC ACQUIRED HÆMOLYTIC ANÆMIA

Synonym.—Hæmolytic Anæmia (type Hayem-Widal).

Idiopathic acquired hæmolytic anæmias may follow an acute, subacute, chronic or relapsing course. Acute cases were formerly distinguished under the names acute febrile anæmia or Lederer's anæmia, but there is no reason for this separation. Nevertheless, the group as a whole is probably not homogeneous. The disease has an affinity to, and in some cases is combined with, thrombocytopenic purpura or agranulocytosis, in both of which conditions morbid antibodies may be present. In rare cases it may be the first manifestation of disseminated lupus erythematosus. Cases are fairly evenly distributed over the decades; females are about twice as often affected as males. In acute cases there may be fever, slight rigor at the onset, headache, lassitude, vomiting and shock. Jaundice may occur and in hyperacute cases there is hæmoglobinuria. Examination of the blood shows a profound anæmia of rapid development. More commonly the progress of symptoms is less urgent and it may be insidious and spread over months. The liver and the spleen may be palpable though the latter is not, as a rule, enlarged to the same degree as in acholuric jaundice. The anæmia may be either normocytic or macrocytic, with an increased reticulocyte count, which in some cases may run at levels over 50 per cent. Spherocytes can usually be seen in the blood film and the osmotic fragility of the red cells is usually increased. Leucocytes and platelets vary in number but are often depressed. The marrow shows great erythropoietic activity of the normoblastic type. The Coombs test is usually positive. In subacute and chronic cases the serum bilirubin is rarely much raised, and clinical jaundice is usually absent.

Diagnosis.—The diagnosis of a hæmolytic anæmia depends on the finding of persistent reticulocytosis and increased erythropoietic activity of the marrow, in the absence of blood loss or leuco-erythroblastic anæmia. The differentiation from other forms of hæmolytic anæmia such as hypersplenism, sporadic cases of acholuric jaundice and symptomatic hæmolytic anæmias is sometimes difficult and may have to depend on the results of therapy or splenectomy. In children two conditions have caused confusion. The first is an acute hæmolytic anæmia due to sucking moth-balls which are made of naphthalene. The second is *idiopathic pulmonary hemosiderosis*, a rare condition in which there are recurrent attacks of effusion of blood into the lungs with associated acute anæmia.

Treatment.—Transfusion may be required in emergency or in refractory cases, but the most effective treatment is with cortisone or corticotrophin, which may need to be given initially in relatively high dosage, e.g., cortisone 300 mg. daily. About three-quarters of the cases may be expected to respond to cortisone, and of those who respond, about half will require a permanent maintenance dosage. No correlation has yet been established between response to cortisone, on the one hand, and the Coombs test, presence of splenomegaly or duration of disease on the other. If cortisone fails, splenectomy should usually be advised, though it should be realised that the more the case departs from the characteristic picture of acholuric jaundice, the less likely is splenectomy to be successful.

LEUCO-ERYTHROBLASTIC ANÆMIA

Synonyms.—Osteosclerotic Anæmia; Myelophthisic Anæmia; Leukanæmia.

Leuco-erythroblastic anæmia is uncommon. It is found typically in association with certain diseases of the bones or bone-marrow, and is characterised by the presence in the peripheral blood of immature red cells and a few immature white cells. The anæmia is characterised clinically not by its severity but by the number of cells in the peripheral blood that normally are confined to the marrow as precursors of the red and white cells of the blood. The colour index is commonly a little below unity

and the mean diameter of the red cells usually within normal limits. Reticulocytes are constantly above normal and nucleated red cells are present, often in large numbers. The leucocyte count is commonly normal or only a little raised, but occasionally very high values may be observed, even above 100,000 per c.mm. There is always an excess of myelocytes and on occasion myeloblasts are also present. The platelet count is usually low. The van den Bergh reaction is usually negative, unless complications are present. The spleen may be palpable, either as a result of myeloid metaplasia or more rarely from neoplastic infiltration. The anaemia has been ascribed to irritation or disturbance in the maturation of the hæmopoietic tissues by the bony disease, but it is essentially hæmolytic in type. It does not respond to iron or liver, and transfusion is the only effective treatment. Leuco-erythroblastic anaemia has been observed in the following conditions, but in some of them it is the exception rather than the rule. In the adult, at any rate, malignant disease is the most important cause of leuco-erythroblastic anaemia.

(a) MARBLE-BONE DISEASE OF ALBERS-SCHÖNBERG.—This is a congenital disease characterised by increased density of the bones, spontaneous fractures, splenomegaly and anaemia which is often of the leuco-erythroblastic type. Symptoms usually begin in childhood with fractures following trivial injury and general backwardness. The anaemia is mainly due to narrowing of the marrow cavity from progressive broadening of the cortex and the radiographic appearances are pathognomonic.

(b) ANÆMIA PSEUDO-LEUKÆMICA INFANTUM.—Under this term von Jaksch described a group of cases of anaemia in children under the age of 3, characterised by anaemia, splenomegaly and leucocytosis, with many immature red and white cells in the peripheral blood. It now appears probable that this syndrome was not a disease entity but included examples of different blood diseases, such as Mediterranean anaemia, which have since been more clearly delineated. The term has therefore fallen into abeyance.

(c) CARCINOMATOSIS OF BONE.—As already emphasised, this is the most important cause of this type of anaemia. Symptoms of the primary growth may be elicited, and radiographic examination will usually reveal the metastases in the skeleton. It is often stated that growths of the thyroid and the prostate are especially liable to metastasise in the bones, but growths of the breast, stomach and lungs are more common causes of leuco-erythroblastic anaemia, owing presumably to their greater frequency.

(d) MULTIPLE MYELOMA.—Only a small percentage of cases of multiple myeloma are accompanied by leuco-erythroblastic anaemia (p. 1184).

(e) CHRONIC NON-LEUKÆMIC MYELOID SPLENOMEGALY.—These are cases in which enlargement of the spleen, often of an extreme degree, occurs as a result of an unexplained myeloid metaplasia. The marrow may be hyperplastic, normal or sclerotic, and neither the marrow nor the viscera show the characteristic changes of leukaemia. The blood picture is commonly of the leuco-erythroblastic type, but cases described as "polycythæmia with osteosclerosis" and "polycythæmia with leukaemia" are probably examples of the same syndrome. In other cases the platelet count is very high, and the names idiopathic thrombocythæmia and megakaryocytic myelosis have been used. The general appearance and behaviour is that of an unusually benign myeloid leukaemia. Although the condition eventually leads to the death of the patient, this rarely happens in less than 5 years, and life may be prolonged for 15 or 20 years after the onset of symptoms. Correct diagnosis is important as cases are often unfavourably affected by irradiation or splenectomy; help may be obtained from radiographs of the skeleton, bone-marrow biopsy or splenic puncture. Treatment is by transfusion; cortisone is usually ineffective. Although fibrosis of the bone-marrow, known as *myelofibrosis* or *myelosclerosis*, is usually present, it is not pathognomonic of chronic non-leukæmic myeloid splenomegaly, occurring also in aplastic anaemia and much more rarely in leukaemia.

(f) LEUKÆMIA AND OTHER CONDITIONS.—In rare instances of true leukaemia

large numbers of reticulocytes and nucleated red cells may appear in the circulating blood. This phenomenon has been described as "mixed leukæmia" when myelocytes and erythroblasts appear in a case of lymphatic leukæmia, or as "leukanæmia" when the disturbance of erythropoiesis is prominent. Some of these are examples of symptomatic hæmolytic anæmia, which will respond to cortisone, but others are leuco-erythroblastic anæmia due to irritation of the bone-marrow by leukæmic deposits. Numerous immature red and white blood cells may very rarely appear in the blood in the course of miliary tuberculosis, syphilis and Hodgkin's disease. The evidence suggests that in all such cases the bone-marrow is involved and the blood disorder is of the leuco-erythroblastic type, but, owing to their great rarity, their pathology has not yet been satisfactorily worked out.

ANÆMIA IN PREGNANCY

The *physiological anæmia of pregnancy* is due to dilution of the blood in pregnancy owing to altered circulatory conditions and increased blood volume. The hæmoglobin rarely falls much below 75 per cent. in healthy women, the colour index is unity and there is no hypochromia or poikilocytosis. It often gives rise to unnecessary anxiety. It is distinguished from pernicious anæmia by its mildness and from iron-deficiency anæmia by the normal colour index. It requires no treatment. The same circulatory phenomena are likely to aggravate the anæmia of iron deficiency in pregnancy, and in women who have suffered from anæmia in a previous pregnancy, or who are unable to take an optimal diet, it is wise to prescribe iron as a prophylactic throughout the period of gestation and lactation. Megaloblastic anæmia is rare in pregnant women in Western Europe and North America, though it is common in tropical or sub-tropical zones. The following causes of megaloblastic anæmia in pregnancy have been differentiated.

1 *Nutritional macrocytic anæmia* is much aggravated by pregnancy, and then assumes a frankly megalocytic type.

2 Pregnancy may occur in a patient with *pernicious anæmia*, or pernicious anæmia may first begin in pregnancy, persisting after gestation, achylia gastrica is present, and subacute combined degeneration may develop.

3 Pernicious anæmia may occur as a temporary phenomenon during pregnancy, disappearing after gestation. This is the true *pernicious anæmia of pregnancy*. It probably occurs in about 1 in 1000 pregnancies in Great Britain. The anæmia does not develop until the last trimester and may not be apparent until the puerperium. The blood picture may not be macrocytic and the diagnosis may depend on examination of the marrow. Pernicious anæmia of pregnancy may be rapidly fatal if it is not effectively treated, and it should therefore be the rule to examine the marrow in severe anæmias in late pregnancy and the puerperium, particularly if there has been failure to respond to iron. The gastric secretion may be normal and the anæmia appears to be due to a disturbance in the metabolism of folic acid. Subacute combined degeneration does not occur. Treatment is by folic acid by mouth in a dosage of 20 mg. a day, which may be gradually tailed off when the anæmia is repaired and the puerperium is over. The disease may or may not recur in subsequent pregnancies.

1. Concentration of the circulating blood, such as occurs in the dehydration of choleraic diarrhoea.

2. Diminution of the oxygen tension in the circulating blood or tissues. Examples of this are—(a) residence at high altitudes; (b) cardiac diseases with cyanosis, especially congenital pulmonary stenosis and acquired sclerosis of the pulmonary arteries (Ayerza's disease, or *cardiacos negros*); (c) conditions interfering with normal pulmonary ventilation, such as emphysema, asthma, fibrosis and neoplasms of the lungs.

3. Chronic poisoning by a number of chemical agents, such as arsenic, phosphorus, carbon monoxide and aniline derivatives.

4. Cirrhosis of the liver, tuberculosis of the spleen and similar conditions associated with splenomegaly or portal stasis, in rare instances.

5. A transient erythrocytosis may occur in the stage of recovery from anaemia. These causes should always be excluded before diagnosing polycythæmia vera; in doubtful cases estimation of the blood volume is helpful, for polycythæmia vera should not be diagnosed unless the blood volume is considerably increased.

1. POLYCYTHÆMIA VERA

Synonyms.—Erythræmia; Osler-Vaquez Disease.

Definition.—A disease characterised by well-marked and persistent increase in the number of red corpuscles, due to an excessive erythroblastic activity of the bone-marrow.

Ætiology.—Erythræmia is a disease of the second half of life. It is a little more common in males, but the difference in the two sexes is not striking. Familial cases of polycythæmia occur; they tend to be mild. Present opinion is that erythræmia is a proliferative condition or benign neoplasia of the bone-marrow, with strong affinities to leukaemia and non-leukaemic myeloid splenomegaly.

Pathology.—The marrow of most of the shafts of the long bones is converted into active red marrow. The spleen is enlarged and engorged, and often contains thrombotic infarcts. The liver is congested, but no anatomical change is present in it.

Symptoms.—The most frequent symptoms are due to disturbance of the cerebral circulation by the increased volume and viscosity of blood. They take the form of nervousness, headache, lack of concentration and vertigo. Sometimes temporary disturbances of vision, aphasia or paralysis occur, which recover completely in a few hours. Itching of the skin, particularly after a hot bath, is a common complaint. Other symptoms are loss of weight and strength, shortness of breath on exertion, angina of effort and abdominal pain or dyspepsia caused by the splenic tumour. The three cardinal signs are rubor, splenomegaly, and polycythæmia. There is cyanosis of the exposed surfaces, especially the cheeks, the tip of the nose and the ears. The colour varies with the temperature, being scarlet in a warm atmosphere and dark blue in the cold. The eyeballs are often bloodshot, the conjunctivæ deep red, and the retinal vessels engorged and tortuous. Papilloedema does not occur in polycythæmia vera and its presence would suggest either that the polycythæmia was complicated by venous thrombosis or that it was secondary to intracranial or pulmonary disease. The spleen is palpable in three-quarters of the cases; it rarely extends beyond the umbilicus and varies in size, shrinking after a hæmorrhage or successful treatment. The liver is palpable in about one-half the cases. The urine may contain a little albumin. The blood contains from 7 to 14 million red corpuscles per c.mm. and 17 to 25 g. hæmoglobin per 100 ml. (120 to 170 per cent.). The red cells are usually smaller than normal, and the colour index is less than unity. The white cells are over 10,000 per c.mm. in three-quarters of the cases but they rarely reach 50,000. The reticulocytes are normal but the platelets may be much increased in number.

Complications.—The most important complications are vascular, and result

from the increased volume and viscosity of the blood and its sluggish flow. It is noteworthy, however, that hypertension is no more common than in normal individuals in the same age-groups. Not uncommonly there are massive hæmorrhages, especially from the stomach, but also from the nose, lungs, bowel, uterus and bladder or internally. Thrombosis is not infrequent, and in the cerebral vessels or the portal vein its consequences may be grave. Symptoms of peripheral vascular disease are frequent, though they may improve strikingly on restoration of the blood to normal. Peptic ulcer is probably a little commoner than in normal people. When the illness runs a long course leukaemia, myelosclerosis, purpura hæmorrhagica and anaemia may intervene, but it is not clear whether these conditions are the effect of the primary malady or of prolonged depression therapy.

Course and Prognosis.—So long as the blood count is abnormally high, there is always the immediate danger of death from one of the vascular accidents. In cases controlled by effective treatment, the expectation of life is probably not greatly reduced and is comparable to that of diabetics treated with insulin. Spontaneous remissions are described, and in any large series, spent cases are found in which the disease process appears to have burnt itself out, though the spleen remains enlarged. In properly treated cases the most serious risk is leukaemia.

Treatment.—Whatever treatment is eventually used, it is best to begin by removing the excess of blood by bleeding. A pint of blood should be removed twice weekly until the hæmoglobin falls below 14.5 g (100 per cent) and the hæmatocrit below 45 per cent. Frequently 10 or 12 successive venesections are needed before this happens. The blood may then be maintained at this level by venesection at longer intervals, but this has the disadvantage of depleting the patient of iron and protein. Radioactive phosphorus is the treatment of choice. A first course of 3.5 to 4 millicuries is given and then no more for 3 months. At the end of that time, if the count is above 6 million red cells per c.mm., a second course of 1 to 3 millicuries is given, and some patients need a third course 3 months later. Roentgen rays may be used in a similar manner, though they are less convenient than radioactive phosphorus, and less certain in effect than in leukaemia. The rays should be applied over the long bones and the chest. Treatment by any form of ionising radiation probably increases the incidence of leukaemia and malignant disease, but it appears to be justified by the results. Chemotherapy, with arsenic, phenyl hydrazine, or nitrogen mustard is now rarely employed if radioactive phosphorus, or Roentgen rays are available.

2 METHÆMOGLOBINÆMIA AND SULPHÆMOGLOBINÆMIA

Synonym.—Enterogenous Cyanosis

Definition.—A condition characterised by cyanosis without cardiac or pulmonary lesions, associated with the presence of methæmoglobin or sulphæmoglobin in the circulating red cells.

Ætiology.—In the vast majority of cases the condition is due to the use of drugs, especially aniline derivatives, and it has become much more common since the introduction of the sulphonamide group. Other drugs which have been incriminated are acetanilide, phenacetin, antipyrine, Trional, sulphonal, potassium chlorate and nitrites. Methæmoglobinæmia is produced by the direct action of the chemical or a breakdown product of it on the red cells. In sulphæmoglobinæmia the chemical sensitises the red cells, so that the hæmoglobin combines with hydrogen sulphide absorbed from the intestine. Sulphæmoglobinæmia is therefore much more likely to develop in constipated patients. A common sequence of events is constipation, headaches, the use of headache powders which contain phenacetin or acetanilide, and sulphæmoglobinæmia. In very rare cases methæmoglobinæmia occurs spontaneously, apparently as a result of excess production and undue absorption of nitrites.

from the gastro intestinal tract this condition is known as *enterogenous cyanosis*. Equally rare is a familial form of methæmoglobinæmia attributed to an inborn error of metabolism—*hereditary methæmoglobinæmia*. Chronic methæmoglobinæmia and sulphæmoglobinæmia are more common in women than men, and should always arouse suspicion of drug addiction hysteria or malingering.

Symptoms—The degree of cyanosis is sometimes out of proportion to the amount of methæmoglobin or sulphæmoglobin present and it is probably aggravated through absorption by the red cells of coloured derivatives of the drugs themselves. The colour varies from a slight muddiness of the complexion to a deep blue. In marked cases the appearance of the patient is indeed ghastly, and yet it is belied by the comfortable general condition the absence of any respiratory distress and the extreme rarity of a fatal issue. In acute cases there may be no symptoms. In chronic cases the patient complains of weakness nervousness vertigo or fainting attacks palpitation, headache and constipation. The blood may show a slight polycythæmia.

Diagnosis—The diagnosis depends on the spectroscopic examination of the blood for methæmoglobin or sulphæmoglobin. The brown colour of the blood can often be recognised with the naked eye. Methæmoglobinæmia in which the altered hæmoglobin is within the corpuscles must be distinguished from methæmalbuminæmia in which altered hæmoglobin is present in the plasma, in the latter, there is no cyanosis and the patient may be jaundiced. The use of drugs should always be suspected especially in chronic and apparently inexplicable cases in women. It is surprising how skilfully they deceive their attendants and escape detection. I have known more than one woman who has lived many months in hospital and has been shown at medical meetings as a rare and mysterious case when all the time the symptoms were being produced by a bottle of phenacetin tablets concealed in the locker.

Prognosis—In patients who are anæmic or who have to work at a high altitude the condition may encroach dangerously on the reserve of functioning hæmoglobin. In other respects it is harmless.

Treatment—Recovery occurs spontaneously in 24 to 72 hours after the drug is discontinued. The cyanosis can be promptly relieved by the intravenous injection of methylene blue 1 or 2 mg per kg, but it will return again if the offending drug is continued. It can be prevented however by the continuous administration of methylene blue by mouth gr 1 or 2 four hourly. Large doses of ascorbic acid are also effective.

LEUCOCYTOSIS

It is important to be familiar with the normal fluctuations of the white cells. In healthy individuals the total number of white cells may vary from 4000 to 11 000 per c mm, the average being 7500. A typical differential count is neutrophils 66 per cent eosinophils 2.5 per cent, basophils 0.5 per cent, lymphocytes 24 per cent monocytes 7 per cent, but there are great physiological variations which are best illustrated by the absolute values of the different cells. The total number of neutrophils may vary from about 1500 to 7500 eosinophils from 0 to 400 basophils from 0 to 200, lymphocytes from 1000 to 4500 and monocytes from 0 to 800. The total white count is at a minimum or basal level when the subject is at rest in the morning activity mental or physical increases it by 60 or 100 per cent. in addition there are rhythmical fluctuations in the number of polymorphonuclears, lymphocytes and monocytes which are probably associated with the replacement of dead or emigrated cells. It is unwise to draw far reaching conclusions from a single count of the white cells and the test should always be repeated when an anomalous result is obtained or when it is uncertain whether the figures fall within normal limits. The most obvious task of the white cells is to protect the body from attack

and invasion by bacteria or similar agencies. They may be compared with a standing army which performs no useful service in times of peace, but which possesses great reserves which may be mobilised in time of war. We might press the analogy further and compare the three main groups of blood cells, the granulocytes, the lymphocytes and the monocytes, with the different fighting branches, for just as different types of warfare require different arms, so the three main groups of blood cells show independent variations in the various phases of an infection, and respond differently to different kinds of disease. An increase in the neutrophil leucocytes should strictly be called neutrophil leucocytosis or neutrophilia, but when the term leucocytosis is used without qualification it is taken to mean a neutrophil leucocytosis. Leucocytosis occurs physiologically during the later stages of pregnancy and for about a week after delivery, in the newly born infant; and after exercise, as many as 35,000 cells per c mm. having been found after violent exertion. The causes of pathological leucocytosis are

- 1 Haemorrhage, or trauma in which tissues are injured and blood is extravasated
- 2 Acute infections, especially by the pyogenic cocci
- 3 Acute intoxications, such as diabetic coma, uræmia, gout, lead colic, coal gas poisoning and poisoning by a number of organic and inorganic substances
- 4 Malignant disease, especially when the tumour grows rapidly, or involves the alimentary tract or the bone marrow, and some cases of Hodgkin's disease

The number of white cells in these conditions commonly varies from 12,000 to 40,000 per c mm., according to the acuteness of the infection or intoxication, and the patient's ability to respond, in exceptional cases the count may even exceed 100,000. The neutrophils are less mature than normal, or are altered by the toxæmia, so that many of the cells have only one or two lobes to their nuclei—a phenomenon described as the "shift to the left". In profound infections in which the patient's resistance is overcome there may be no increase in the total number of white cells but a considerable shift to the left is present, this is a sign of very ill omen. When there is a considerable leucocytosis, as in pneumonia and scarlet fever, small numbers of myelocytes may appear in the peripheral blood.

EOSINOPHILIA

The function of the eosinophil cells is not known, though it is suggested that they protect the body against the absorption of foreign proteins or of abnormal products of protein metabolism. Their number is increased by certain drugs, such as emetine and also by feeding with whole liver. They are decreased in surgical shock, and by the hormones corticotrophin and cortisone. There is a rare condition of hereditary eosinophilia which sometimes manifests itself in different members of a family, and in which the normal proportion of eosinophils and neutrophils is reversed, in such cases infection is attended by a neutrophil leucocytosis and a temporary diminution of the eosinophilia. A constitutional tendency of the same kind is probably present in a number of individuals, and explains the high eosinophilia that may sometimes appear from trivial or unusual causes. In the symptomatic eosinophilia tabulated below it is rare for the total white count to be much increased, or for the eosinophils to exceed 20 per cent., but occasionally they may constitute over 50 per cent. of a total white count of 50,000 to 100,000. The eosinophils are usually increased in

- 1 Infestation by parasites, especially hydatid cysts, ancylostomiasis and trichinosis. *Löffler's syndrome*, a condition in children in which transient pulmonary infiltrations are associated with blood eosinophilia, has been ascribed to the migration of larvæ of *ascaris lumbricoides* through the lungs. *Tropical Eosinophilia* (Wein-garten's syndrome) is a very similar syndrome which has been observed particularly

in India and Ceylon, and in which eosinophilia is associated with asthma and bronchitis. The eosinophil count is of the order of 40 to 80 per cent.—or even higher. In some cases the symptoms have been ascribed to infestation of the bronchi and bronchioles by mites. Tropical eosinophilia responds extremely well to a course of injections of neoarsphenamine and I have seen an equally favourable result in a woman with eosinophilic bronchitis who had never been in the tropics.

2. Convalescence from acute diseases; they are diminished in the acute stage, except in cases of scarlatina in which there is a slight eosinophilia at the time of the eruption, and sometimes in acute rheumatism.

3. Allergic states, such as asthma and hay fever.

4. In many skin diseases.

5. In Hodgkin's disease in about one-quarter of the cases, but rarely to a high degree, in polyarteritis nodosa, and in rare cases of malignant growths, more especially when the peritoneum is involved.

6. In myeloid leukaemia and erythraemia.

EOSINOPHILIA WITH SPLENOMEGALY

Synonym.—Eosinophilic Leukaemia.

This is an uncommon syndrome in which enlargement of the spleen is associated with persistent eosinophilia; the liver and the lymph glands may also be palpable. The total white count is usually between 10,000 and 25,000, but it may exceed 50,000 cells per c.mm.; eosinophils constitute from 20 to 80 per cent., the majority being mature and only a small fraction myelocytes. Anaemia, if present, is of moderate degree. Post mortem the hyperplastic bone-marrow is seen to be filled with eosinophils in all stages of development. Eosinophil cells are present in the other organs, especially the spleen and the lymph glands, but here they are mainly adult cells. Areas of hæmorrhage and fibrosis may be found in the spleen and the lungs, and granulomatous tumours have also been observed. The benign course of the disease in many instances, the absence of anaemia and the small percentage of myelocytes in the blood and tissues are arguments against regarding the condition as a true eosinophilic leukaemia. It is probably not a disease entity, but a syndrome of varied ætiology. Some cases are examples of hereditary eosinophilia in its severer form; others are acquired on the basis of asthma and bronchitis, syphilis, malaria, hepatic cirrhosis, myeloid leukaemia, Hodgkin's disease and other known causes; and a few cases remain obscure. The prognosis is moderately good, but death may occur from intercurrent infection. Cortisone or corticotrophin should be tried. Splenectomy is contraindicated, as it aggravates the eosinophilia. Great improvement follows antisyphilitic treatment in cases with a positive Wassermann reaction.

LYMPHOCYTOSIS

Little is known about the function of the lymphocytes, though they are believed to play an important part in the protection of the mucosæ and the formation of antibodies. They are increased by exposure to ultra-violet light, and diminished by excessive irradiation, vitamin deficiency and the hormones corticotrophin and cortisone. Lymphocytes are more numerous in the blood of children than of adults, constituting from 40 to 60 per cent. of a total count of 7000 to 9000 white cells per c.mm., and their reactions to disease are much greater in early life. There are few infections in childhood which may not now and again be associated with an extraordinarily high lymphocyte count. The lymphocytes are especially increased in whooping-cough, chicken-pox, small-pox, typhus, malaria and most constantly in glandular fever (acute mononucleosis). In isolated instances of these various infections, the lymphocytes may rise as high as 75 per cent. or more of a total count of 100,000 white cells per

c.mm., and leukaemia may be suspected. Usually the absence of anaemia should quiet this suspicion. The lymphocytes are moderately increased in the stage of healing of acute infections, and in tuberculosis which is progressing favourably. They are diminished in miliary tuberculosis and lesions of the lymphoid tissues, such as glandular tuberculosis, Hodgkin's disease, carcinoma and lymphosarcoma.

MONOCYTOSIS

The monocytes are increased during and after the crisis in acute infections, and also in active tuberculosis, sympathetic ophthalmia and undulant fever. Very high counts are occasionally obtained in miliary tuberculosis and infective endocarditis.

BASOPHILIA

The basophils are moderately increased in a number of diseases of the blood-forming organs, such as leukaemia, erythraemia and acholuric jaundice. The increase of basophil cells in myeloid leukaemia is sometimes of a diagnostic importance, as it may be the only abnormality present during a remission.

LEUCOPENIA

Leucopenia implies a condition in which the total white cell count is reduced below the normal range, *i.e.* below 4000 per c.mm. Granulocytopenia or neutropenia indicates a similar diminution in the number of granulocytes or neutrophils respectively, *i.e.* less than 1500 neutrophils per c.mm. While the majority of infections induce a leucocytosis, it is characteristic of certain diseases that the white count is normal or diminished. The most important infections in which there is leucopenia are the enteric fevers, undulant fever, influenza and measles. Leucopenia may also occur in septic infections when the resistance is overwhelmed by the severity of the infection; it is nevertheless unusual for the white blood count to sink to the low levels characteristic of agranulocytosis, and a total white count below 2500 should arouse the suspicion of an underlying abnormality in the blood-forming organs. Leucopenia resulting from septic infections differs from agranulocytosis in the presence of septic foci, positive blood cultures, and at necropsy the septic type of splenitis. As might be expected, leucopenia occurs in cachectic and debilitated states and in diseases of the blood-forming organs in which the leucopoietic tissues are depressed. There is a temporary fall in the number of leucocytes in the peripheral blood in anaphylactic shock and similar conditions, owing to the collection of the cells in the internal organs.

In the conditions already discussed, the leucopenia is usually moderate in degree and produces no obvious clinical effects, the symptoms being those of the primary disorder. Leucopenia of a much more severe degree occurs in aplastic anaemia and leucopenic leukaemia. The bacteria which are constantly present on the surfaces of the body are then able to invade the tissues, and the trivial infections to which all of us are exposed take on a malignant character. The most common invaders are Vincent's organisms, with the production of fetid ulceration in the mouth and throat or elsewhere. Lesions such as cancrum oris, noma and putrid sore throat rarely develop unless the white blood cells are depressed. Such extreme leucopenia is nearly always accompanied by signs of damage to the other haemopoietic tissues, such as anaemia and a tendency to bleed. The leucopenia is indeed only one manifestation of a general depression of marrow function. There are, however, cases in which the lesion is strictly confined to the white cells and the leucopoietic tissues, so that the red cells and platelets remain intact. It is to cases of this last type that the

term *agranulocytosis* should strictly be confined, as they form a clinical entity with characteristic pathological changes, but the term is often loosely applied to any condition in which the white cell count is greatly depressed, and necrotic ulceration is present

AGRANULOCYTOSIS

Synonyms—Malignant Neutropenia, Primary Granulocytopenia, Agranulocytic Angina

Definition—A disease characterised by profound leucopenia, an acute febrile illness, necrotic ulcerations and a high mortality

Ætiology.—The majority of cases are due to an idiosyncratic reaction to drugs especially amidopyrine and the related phenylbutazone, the sulphonamides and the related thiourea derivatives, and troloxidone (Tridione) and related anti epileptic drugs. During the active phase of agranulocytosis following the administration of amidopyrine, an antibody can be demonstrated in the plasma which agglutinates the white cells. It is assumed that this antibody leads to greatly increased peripheral destruction of the granulocytes with consequent depletion and exhaustion of the bone marrow. Leuco agglutinins have also been demonstrated in other forms of agranulocytosis, including some in which there is no history of taking drugs, and the Coombs test may be positive

Patients who have an idiosyncrasy to amidopyrine may become sensitive to the drug after taking quite a small quantity, and in the sensitised subject a dose as small as 0.2 g. may be followed by an abrupt diminution in the white cells and changes in the marrow. Agranulocytosis therefore occurs typically in patients who are taking amidopyrine in small doses or at long intervals. When a patient has taken a total of 50 g. amidopyrine with impunity (in divided doses, of course) it becomes progressively less likely that he will become sensitive, though there can be no absolute surety of safety. The position with the sulphonamides is different. Agranulocytosis from the sulphonamide group rarely occurs until at least 30 g. of the drug has been taken. It is therefore infrequent before the tenth day and is more likely to be found with second or later courses of treatment. With thiouracil agranulocytosis occurs most commonly in the second month of treatment, but it has been observed after both short and prolonged periods of administration, and at all dosage levels. Agranulocytic syndromes may also occur after most of the poisons mentioned under aplastic anaemia (p. 738), but they are rarely so clear-cut and tend to be complicated by anaemia and hæmorrhage. Chronic and recurrent types of agranulocytosis are occasionally met with, especially in females, for which no explanation can be found. There is also a very rare disease, *primary splenic neutropenia*, in which chronic agranulocytosis occurs in association with splenomegaly, without cirrhosis or drug and bacterial idiosyncrasies, and is completely relieved by splenectomy. This may be regarded as the counterpart of idiopathic hæmolytic anaemia and essential thrombocytopenic purpura.

Pathology—Necrotic, ulcerative or gangrenous lesions are present, most constantly in the mouth and pharynx, but they may affect any part of the alimentary canal, the rectum and the vagina. Oedematous or brawny swellings may be present about the teeth, the neck, in the subcutaneous tissues or elsewhere. The bone marrow contains its normal complement of megakaryocytes, and erythropoiesis is normal, but granular leucocytes and myelocytes are absent, in cases dying early small islands of myeloblasts are seen, but in the later stages these too may disappear and the only white cells seen in the marrow are focal accumulations of lymphocytes.

Symptoms—In cases due to amidopyrine, there is often a long history of mental or physical over exertion followed by chronic fatigue, loss of weight and vague pains in the limbs. If the blood is examined in this prodromal phase, leucopenia of moderate degree will be found. Acute symptoms are often precipitated by dental extraction

or an influenzal attack. The onset is abrupt, sometimes with rigors, and the patient complains of aching pains in the limbs and sore throat, and is rapidly prostrated. The temperature is high, ranging from 100° to 105° F. In the majority of cases ulcero-membranous lesions soon appear on the tonsils and gums, and the cervical glands may be enlarged, with surrounding brawny induration. As already indicated, other mucous surfaces may be involved, and in rare cases the sole infective lesion may be a mild redness of the throat without any other tissue or blood infection. The patient is pale but not anæmic. The liver and the spleen may be palpable, and jaundice is an occasional complication. As the disease advances, the usual symptoms of a profound toxæmia appear. Examination of the blood at this stage shows a total white count below 2000, often only a few hundred cells per c.mm.; the reduction affects especially the granulocytes, which may be diminished to about 5 per cent. or even completely absent.

Diagnosis.—Cases arising in the course of another illness which has been treated by amidopyrine or one of the sulphonamides may be very difficult to recognise. The diagnosis depends chiefly on the history and the blood picture. Specific inquiry should be made as to the use of amidopyrine, which is contained in many analgesic and hypnotic preparations. The author has seen several cases in which the amidopyrine hypothesis had been discarded, but further questions revealed the fact that the drug had indeed been used or was still being used. Aplastic anæmia and leukæmia can be excluded by the blood picture, as the red cells and platelets are not affected in agranulocytosis, and there are no primitive white cells such as appear in acute leukaemia.

Prognosis.—Spontaneous recovery from an acute attack may occur, but the mortality of untreated cases is about 75 per cent. The results of current therapy have not yet been appraised but in cases diagnosed early the mortality should not exceed 25 per cent.

Prophylaxis.—No one should ever be given a prescription which allows amidopyrine to be taken without close medical supervision. Patients taking phenylbutazone, anti-epileptic or anti-thyroid drugs should be warned to report at once if they suffer from fever, sore throat or other untoward symptoms. If drugs of the sulphonamide group are given for more than a week, the blood should be examined at regular intervals. The occurrence of drug fever 7 to 10 days after beginning sulphonamide treatment may herald the onset of agranulocytosis. It is not known how long the patient remains sensitive to drugs capable of producing agranulocytosis but it may be for the rest of his life. After an attack, therefore, the patient should be specifically told not to take the drug again.

Treatment.—The first step is the removal of the cause where this can be identified as a drug. At the same time corticotrophin or cortisone should be given in full doses to accelerate the disappearance of the morbid antibody and the recovery of leucopoiesis. Penicillin or other antibiotic should be given in large doses and in the majority of cases the infection will clear up in 3 to 10 days. For local treatment penicillin lozenges may be used or the mouth and throat may be frequently washed out with a hypochlorite solution. In severe cases the mouth may be sprayed with a saturated solution of potassium chlorate, and ulcerated areas then swabbed with a solution of copper sulphate, 10 grains to an ounce of water. Abscesses and areas of cellulitis should be drained but only essential surgery should be done until the white count is stabilised at a normal level. In chronic and recurrent cases of granulocytopenia, splenectomy is of value in the small group of cases in which the spleen is enlarged and the bone-marrow is hypercellular.

LEUKÆMIA

Synonym.—Leukosis.

Definition.—Leukæmia is a morbid condition characterised by widespread

hyperplasia of the leucopoietic tissues, either myeloid or lymphatic, which is usually associated with qualitative and quantitative changes in the white cells of the circulating blood.

Ætiology.—The ætiology is unknown, and the disease appears to occupy an intermediate position between the reaction to infections and noxious agencies on the one hand and the true neoplasms on the other. Leukæmia occurs in the lower animals also, and (like the sarcomata of these animals) it is sometimes transmissible by cell-free filtrates. In its more acute forms in man it often resembles an infection, and very similar changes in the blood and the blood-forming organs may sometimes be produced by infections and similar clearly apprehended agencies; it is difficult, however, to reconcile the tumour-like growths which sometimes develop in leukæmia with a hypothesis of infection. It differs from the ordinary neoplasms in being a system-disease, and affecting the whole organ simultaneously. The neoplastic hypothesis presents fewer difficulties, the diffuse character of the lesion being explained by the labile character of the leucopoietic tissues and being paralleled by the diffuse carcinomas of the breast and the cirrhotic liver. In experimental animals leukæmia has been induced by indole, benzol and tar, and in man it has been thought to be unduly frequent in those whose work exposes them to benzol, Roentgen rays and radium. There has been a real increase in leukæmia in the last 50 years and it has been speculated that this may be due to the increased opportunities for contact with synthetic chemicals in our present civilisation. In experimental animals stocks with a high incidence of leukæmia can be produced by selective breeding, and in man it is probable that the disease only occurs in those with the appropriate genetic make-up.

Classification.—We might expect to find forms of leukæmia corresponding to each of the different types of white blood cell, and classify them accordingly. In practice it is found that the only forms of leukæmia which occur at all frequently are those which involve predominantly the neutrophils and their precursors, or myeloid leukæmia, and those which involve the lymphocytes, or lymphatic leukæmia. Eosinophilic leukæmia has already been discussed; in exceptional cases of myeloid leukæmia basophil cells may predominate. Monocytic leukæmia has recently attracted much interest, but many cases so described are actually myeloblastic leukæmia, and in the majority, at any rate, myeloblasts or myelocytes as well as monocytes are present in the blood and tissues. In cases in which monocytes predominate, the leukæmia is usually acute or subacute, with fever, severe anæmia and necrotic mouth lesions, and a tendency to temporary remissions and aleukæmic phases. In leukæmia the immaturity of the cells is just as important as the type of cell present, and for clinical work the leukæmias are therefore described as chronic myeloid leukæmia, chronic lymphatic leukæmia and acute leukæmia. Whichever strain of cells is affected, the disease breeds true, and the two groups of cells are never involved simultaneously. Confusion is sometimes arisen owing to the ease with which very immature cells of the myeloid series, the myeloblasts, can be mistaken for lymphocytes. The increase in leukæmia in recent years has particularly affected acute leukæmia and chronic lymphatic leukæmia. At present about 40 per cent. of cases are acute leukæmia, 33 per cent. chronic lymphatic and 25 per cent. chronic myeloid.

1. CHRONIC MYELOID LEUKÆMIA

Synonyms.—Myelocytic Leukæmia; Spleno-Medullary Leukæmia; Chronic Leukæmic Myelosis.

Ætiology.—The two sexes are equally involved. The disease is very rare before puberty, and about half the cases begin between 30 and 50, the greatest incidence being between 35 and 55.

Pathology.—The changes which are found in the body are almost confined to the hæmopoietic organs. The bone-marrow is firm and fleshy, pale pink or grey in

colour, rarely of a greenish hue. The predominant cell is the myelocyte, but there are also large numbers of myeloblasts and nucleated red cells. The spleen is usually enormously enlarged, but its outline is preserved; its surface is smooth, its consistence firm, its colour on section a greyish-red, usually mottled with infarcts. Microscopically the Malpighian corpuscles are obliterated, and the pulp is filled with myeloid cells and resembles the bone-marrow. The liver is large, firm and of a pale yellow tint, and its capillaries contain large numbers of myelocytes. The other organs may show anæmia, hæmorrhages and infiltration with myelocytes.

Symptoms.—Early symptoms are easy fatigue, slight loss of weight and strength, and gastro-intestinal disturbances, but the patient may first complain of the enlargement of the abdomen due to the increasing size of the spleen. The anæmia at this time is not marked, indeed the appearance is not infrequently one of good health. Pain in the left side is sometimes felt, either as a result of the dragging weight of the enlarged spleen or from perisplenitis over an infarct. The average duration of symptoms before medical advice is sought is about a year. Fever is commonly slight, and there are often long periods of normal temperature interrupted now and then by small rises of short duration to 101° or 103° F. The basal metabolic rate is increased. Tenderness is often present over the sternum, more marked during exacerbations of the disease.

On examination the striking feature is the size of the spleen. It occupies the greater part of the left side of the abdomen, often reaching to the iliac crest below and the middle line at the umbilicus. It forms a hard smooth tumour, with rounded edges, not tender to palpation and easily recognised by the characteristic notches in the anterior margin. The size tends to vary in the course of the disease, often leading to false hopes as to the efficacy of treatment. Sudden enlargement is due to hæmorrhage or infarction, and marked diminution may occur with the approach of death. The liver is larger than normal, and smooth. The lymph glands are rarely palpable, except sometimes near the end. Impairment of vision may occur from leucocytic accumulations or hæmorrhages in the retina, while involvement of the inner ear may lead to deafness and Ménière's syndrome.

In the later stages the anæmia becomes severe, and cachexia develops. Ascites and œdema make their appearance, the heart weakens and the patient becomes emaciated. Hæmorrhage is frequent, but rarely lethal. Death occurs from exhaustion or from intercurrent infection. It should be noted that infection may produce a temporary improvement in the blood picture, but such a remission is often followed by an aggravation of the disease, which then pursues an acute and rapidly fatal course. Conversion of chronic into acute leukaemia may also happen spontaneously.

The blood.—The principal characteristics are progressive loss of hæmoglobin and of red cells, and increase, frequently enormous, of the leucocytes. The white count ranges from 100,000 to 1,000,000 cells per c.mm., values about 400,000 being most usual. The increase is mainly composed of cells of the granulocyte series. The typical cell is the neutrophil myelocyte, which constitutes 20 to 40 per cent. of the total; but the neutrophil, eosinophil and basophil polymorphonuclears are also increased, eosinophil and basophil myelocytes are present, and occasional myeloblasts are encountered. The anæmia is of the orthochromic type, and as it becomes more severe, anisocytosis and polychromasia develop, and nucleated red cells appear in the blood. The platelets are normal or slightly increased at the beginning of the disease, but decrease in the terminal phase.

Diagnosis.—This is usually made with ease from the characteristic blood picture and the great splenic enlargement, though difficulty may arise when the white cells fall to normal or subnormal values as a result of treatment. In these circumstances the presence of immature white cells and of basophil leucocytes may indicate the correct diagnosis. Myeloid leukaemia usually runs true to type and rarely presents an aleukæmic phase. The differential diagnosis of chronic myeloid leukaemia and

non leukæmic myeloid splenomegaly may be difficult, but in the latter the blood picture is not frankly leukæmic and total white cell counts above 30,000 per c mm. are unusual

Course and Prognosis—Chronic myeloid leukæmia is invariably fatal. The average duration of life is just over 3 years from the onset of the disease, or 2 years after coming under treatment. There is no evidence that treatment prolongs life, though it greatly increases the comfort of the patient. In any large series exceptional cases are observed in which life is prolonged for 10 to 20 years, though one may suspect that most of these are examples of chronic non-leukæmic myeloid splenomegaly. At the other extreme are subacute cases which shade indefinitely into acute leukæmia. The prognosis in an individual case will depend on the general condition of the patient and the presence or absence of cachexia, the degree of anæmia, and the height of the white count, very high and also very low values being unfavourable. Enlargement of lymph nodes and the appearance in the blood of large numbers of myeloblasts are each unfavourable signs. (See also under Treatment)

Treatment—Chronic leukæmia is treated either by the ionising radiations of Roentgen rays and radioactive substances, or by chemotherapy with mitotic poisons such as arsenic, benzol, colchicine, nitrogen mustard, urethane and Myleran. Both types of agent act by disturbing or destroying the proliferating white cells during cell division, or when cell division is about to begin. As a result a temporary remission of the disease is induced. The natural course of chronic myeloid leukæmia is steadily downhill, and during the latter half of the untreated disease the patient is confined to his bed, cachectic and miserable. After a course of treatment with Roentgen rays or chemotherapy, the patient is restored to what he feels his normal condition. The spleen usually remains enlarged and the blood abnormal, but in rare cases the blood returns almost to normal and the spleen recedes beneath the costal margin. Such a remission lasts from a few months to a year, when repetition of the treatment again produces improvement, though not so complete as before. After a varied number of cycles treatment finally becomes ineffective, and a time arrives when, despite all efforts, the patient becomes steadily worse. The period of decline is usually swift and in the majority of cases death occurs within 4 or 5 months of entering this final phase. A patient who has become resistant to radiotherapy may respond to chemotherapy, and vice versa, but the point of attack of the two types of therapy is similar and as a result life can seldom be much further prolonged by alternating treatment in this way.

Irradiation is the treatment of choice. The rays may be applied to the bones or the spleen, or both, though there is some evidence that radiation is most effective when applied over the spleen. The best results appear to be obtained with small doses frequently repeated. Treatment is stopped when the white count has fallen to about 15,000, as the fall may continue for 2 or 3 weeks after cessation of treatment, it should be resumed whenever the white count rises above 50,000 cells per c mm. Radioactive phosphorus may be used instead of Roentgen rays, though it appears to be inferior in value. An initial dose of 1 to 2 millicuries intravenously is followed by 4 doses of 0.5 to 1.0 millicurie at 3 or 4 days' interval, and then 0.5 to 1.0 millicurie is given weekly until the leucocyte count has fallen to 30,000 per c mm.

Other forms of chemotherapy have been displaced by Myleran (1.4 dimethane sulphonyloxybutane) which has a specific action in depressing the production of granulocytes. Treatment which is given by mouth, is begun with a dosage of 4 to 6 mg a day, and if a favourable response is obtained, this may later be reduced and a maintenance dose determined. Thrombocytopenia may develop, even with therapeutic doses, and it is essential to examine the blood weekly until the dosage has been stabilised. The marrow should also be examined at intervals as there is some risk of aplasia. Hormone therapy with corticotrophin or cortisone is of no value in chronic myeloid leukæmia. With successful radiotherapy or chemotherapy, the hæmoglobin

and red cells return spontaneously to more normal levels; iron and transfusion may be useful in accelerating recovery.

2. CHRONIC LYMPHATIC LEUKÆMIA

Synonym.—Chronic Lymphocytic Leukæmia.

Definition.—A chronic overgrowth of the lymphatic tissue throughout the body, accompanied by an increased number of lymphocytes in the blood.

Ætiology.—The disease is one of middle and later life, and is hardly ever met in children. The average age of incidence is 60, over 10 years later than chronic myeloid leukemia. Males are affected about twice as often as females.

Pathology.—Post mortem, the striking feature is the enlargement of the lymph glands and other lymphoid tissues. The glands are seldom larger than a walnut, discrete, homogeneous and pinkish grey on section. The lymphoid tissue of the pharynx is hypertrophied, and lymphoid nodules may be present in the intestines, the kidneys and elsewhere. The liver and spleen are uniformly enlarged, the bone-marrow is hyperplastic and grey or greyish red in colour.

Symptoms.—The disease may be present for months or years before the patient feels it necessary to consult a physician. Swelling of the glands is usually the first symptom to attract attention, or the patient may complain of increasing tiredness and loss of weight. Less frequently enlargement of the tonsils is first noticed, or enlarged glands and spleen are discovered by chance during a routine examination. In exceptional cases a tumour extirpated by the surgeon is found to be a lymphoma, and subsequent examination of the blood reveals chronic lymphatic leukemia. Other early symptoms are itching eruptions of the skin, and impotence.

In typical cases all the superficial lymph glands are enlarged. The enlargement is moderate and the glands are rarely so big as in Hodgkin's disease or lymphosarcoma. They are freely movable and not adherent to one another, moderately hard and do not alter in consistence during the course of the disease. Spontaneous fluctuations in their size may occur. In atypical cases only one group of glands may be enlarged. The tonsils may be hypertrophied, the spleen is nearly always palpable, though it does not often extend more than a hand's breadth below the costal margin, and the liver is enlarged. Tenderness of the sternum or of the long bones is unusual. Hyperplasia of the lymphoid tissue in various parts of the body may lead to the formation of tumours or other unusual symptoms. Nodular lesions, infiltrations and actual tumours may develop in the skin. Enlargement of the thymus and the mediastinal lymph glands may produce the signs of an intrathoracic tumour. Lymphomata may develop in the breast or other organs. The salivary and lacrimal glands may be symmetrically enlarged, producing one of the varieties of Mikulicz's syndrome.

The blood.—The red cells and hæmoglobin are unaffected in the early stages, but later severe anemia develops, with anisocytosis, polychromasia and nucleated red cells. The platelets are unaffected till the end, and hæmorrhage is rare. The total white count is increased, usually to about 200,000 cells per c.mm., but not to the high level seen in chronic myeloid leukemia. Lymphocytes predominate and may constitute 95 to 99 per cent. of the white cells. The majority are small lymphocytes, though a few large lymphocytes are nearly always present. The nuclei may be more deeply indented than normal, and azuro-granules are usually absent. The absolute number of polymorphs is unaltered, and no myelocytes are present. It is probable that the proliferation of lymphoid tissue in the glands and elsewhere may precede by some time the increase of lymphocytes in the blood-stream. In rare cases the blood is normal when the patient first comes under observation, but later the characteristic picture develops (*aleukemic leukemia*); or the total white count may not be increased, though there is a high percentage of lymphocytes (*leucopenic leukemia*).

Diagnosis.—Only in the rare aleukemic cases is diagnosis difficult. Points of

importance are the generalised enlargement of the lymph glands, their uniform consistence and moderate size, and the enlargement of the liver and spleen. Biopsy of a gland or sternal puncture may assist.

Prognosis.—The disease is invariably fatal. The average duration is $3\frac{1}{2}$ years from the onset, or about 18 months after coming under treatment. A few cases are more chronic, and exceptionally life may be prolonged for 10, 15 or 20 years. Death occurs from cachexia, hæmorrhage or most commonly from intercurrent infection, sepsis being a very dangerous complication. It is doubtful whether treatment greatly modifies the course of the disease.

Treatment.—Roentgen rays should be applied to the lymph glands if the enlargement is troublesome. Radioactive phosphorus, general irradiation or irradiation of the spleen is rarely as effective as in chronic myeloid leukaemia; it may be followed by depressing reactions and is often better avoided if the patient is maintaining a reasonable level of hæmoglobin. The hormones corticotrophin and cortisone are less effective in chronic than in acute lymphatic leukaemia; they are most useful in cases complicated with skin eruptions or with a hæmolytic type of anaemia. The chemotherapeutic drugs, nitrogen mustard and its derivatives, tri-ethylene-melamine and urethane should theoretically be of value but they have likewise proved rather disappointing; they are particularly indicated in the later stages when there is widespread infiltration. Transfusion has been the most useful therapy in the author's experience and it may be followed by a sustained improvement. If the effect of transfusion is not well maintained, hypersplenism should be suspected and splenectomy may be contemplated, but operation is not justifiable in cachectic patients. In all forms of leukaemia, and especially in chronic lymphatic leukaemia, it is important to assess therapy in terms of its effect on the patient as a whole and not merely on the disordered white cells.

3. ACUTE LEUKÆMIA

Ætiology.—The two sexes are approximately equally affected. Acute lymphatic leukaemia is most common in the first 5 years of life; the incidence then falls and about age 20 reaches a uniform level comparable with that of the myeloid and monocytic forms. Acute myeloid and acute monocytic leukaemia are fairly evenly distributed over the decades.

Symptoms.—The onset is usually abrupt and more than half the cases begin with symptoms regarded as a cold, influenza or bronchitis; it is only when the infection fails to respond to treatment and the patient remains prostrated that a more serious disease is suspected. Other early symptoms are ulcerative stomatitis, or tonsillar enlargement with sore throat, and some cases first come under the physician's care after a prolonged hæmorrhage from tonsillectomy, dental extraction or some trifling operation, which has left the patient exsanguinated. The course of the disease varies from fulminating cases in which the patient succumbs within a week, through cases of average acuteness with a duration of less than 2 months, to subacute cases which shade indefinitely into chronic leukaemia. Usually the rapid development of anaemia, weakness and loss of weight soon compels the patient to take to his bed. He complains of sore throat, headache and pain in the bones. The temperature becomes high and purpuric manifestations set in, which aggravate the anaemia or bring the patient's sufferings to an abrupt termination by loss of blood or cerebral hæmorrhage.

On examination the extreme pallor and the enlargement of the superficial lymph glands, especially those in the neck, first attract attention. The pallor is most striking when there are in addition purpuric hæmorrhages into the skin, varying in extent from a pinpoint to large patches which may break down and ulcerate. The size of the spleen varies; usually it is easily palpable, but it may not be felt, or it may be greatly enlarged. The liver may be enlarged. The lungs may show bronchitis,

broncho-pneumonia, or pleurisy, with or without effusion. Pericarditis and endocarditis may occur. The mind usually remains clear to the end. Certain symptoms may be so prominent as to colour the whole clinical picture and give a special aspect to the disease. In the angrinal type, there is necrotic ulceration of the tonsils or other areas of the buccopharyngeal mucous membrane, or bleeding from the gums, complicated by secondary infection. In the hæmorrhagic type, purpura and hæmorrhages are the predominant features, and the disease may be mistaken for purpura hæmorrhagica. There may be hæmorrhage from any of the mucosæ, and in one of my cases there was so much blood in the urine that firm clots formed in both pelvis and ureters, leading to death from suppression of urine. Disturbances of vision or deafness may result from hæmorrhage into the retina or the labyrinth. The fever and slight splenomegaly may be suggestive of some systemic infection, and there may be leucopenia and an eruption resembling the rose spots of typhoid fever. Bone pains may suggest the diagnosis of acute rheumatism, and there may even be serous effusion into the joints.

In the more subacute forms of the disease, tumours may develop in various parts of the body. They are composed of undifferentiated white cells and infiltrate the surrounding tissues like a malignant growth. Plum-coloured nodules appear in the skin or in the gastro intestinal tract, in the latter situation leading to vomiting or profuse diarrhœa, often blood-stained in character, or to intussusception of the bowel. In the abdomen or in the mediastinum large growths may develop from the lymph nodes or the thymus, compressing and infiltrating the adjacent structures. Tumours of the bones have been distinguished by the special title of *chloroma*, owing to the greenish colour sometimes seen in the freshly cut surface of the growth. They have a predilection for the subperiosteum of the orbit, and cause headache, deformity of the temporal and frontal bones, exophthalmos, proptosis, papilloedema and swelling of the veins of the head, neck and face. They may, however, occur in other parts of the skeleton, and sometimes seem to arise within the bone, which is expanded over them in a brittle shell. The spinal meninges may be invaded, with consequent transverse myelitis, while infiltration of the nerve roots leads to peripheral nerve palsies. It is a curious feature of these neoplastic phenomena that they often begin with a very atypical blood picture, the total white count not being greatly increased and in rare cases the differential count being normal at the onset, though the typical blood picture of leukæmia appears later.

Hæmatology and Pathology.—The outstanding feature of the blood in acute leukæmia is the presence of a large number of mononuclear cells of a primitive type, except in rare cases of acute lymphatic leukæmia, in which the predominant cells may be typical lymphocytes. The classification of the cells is not easy and sometimes they are too primitive to be identified. Figures for the incidence of the different types of acute leukæmia in recent series are 40 to 55 per cent. lymphatic, 25 to 33 per cent. myelogenous, and 20 to 25 per cent. monocytic. The total white count is rarely high in the early stages of the disease, usually not exceeding 25,000 to 30,000 per c mm., but, as a rule, there is a rapid rise to 100,000 or more before the termination. Primitive cells constitute 90 per cent. or more of the white blood cells. Sometimes the total number of white cells is diminished and the count may be below 1000, the majority of the cells being myeloblasts. Such *leucopenic* cases are very prone to necrotic ulcerations and infectious complications. Much more rarely both the total and the differential white count are normal at the onset of the disease, as if the morbid process had not yet invaded the blood stream—*aleukæmic leukæmia*. The overgrowth of the primitive white cells in the marrow and the hæmorrhages soon lead to a profound anæmia, usually of a normocytic type. The number of platelets is diminished in almost all cases, and sooner or later this is reflected in the hæmorrhagic character of the disease. The bleeding time is prolonged, the tourniquet test is positive, and the clot may not retract well.

importance are the generalised enlargement of the lymph glands, their uniform consistence and moderate size, and the enlargement of the liver and spleen. Biopsy of a gland or sternal puncture may assist.

Prognosis—The disease is invariably fatal. The average duration is $3\frac{1}{2}$ years from the onset or about 18 months after coming under treatment. A few cases are more chronic and exceptionally life may be prolonged for 10, 15 or 20 years. Radioactive phosphorus, general irradiation or irradiation of the spleen is rarely as effective as in chronic myeloid leukaemia, it may be followed by depressing reactions and is often better avoided if the patient is maintaining a reasonable level of hæmoglobin. The hormones corticotrophin and cortisone are less effective in chronic than in acute lymphatic leukaemia, they are most useful in cases complicated with skin eruptions or with a hæmolytic type of anæmia. The chemotherapeutic drugs nitrogen mustard and its derivatives, tri ethylene melamine and urethane should theoretically be of value but they have likewise proved rather disappointing; they are particularly indicated in the later stages when there is wide spread infiltration. Transfusion has been the most useful therapy in the author's experience and it may be followed by a sustained improvement. If the effect of transfusion is not well maintained hypersplenism should be suspected and splenectomy may be contemplated but operation is not justifiable in cachectic patients. In all forms of leukaemia and especially in chronic lymphatic leukaemia it is important to assess therapy in terms of its effect on the patient as a whole and not merely on the disordered white cells.

3 ACUTE LEUKÆMIA

Ætiology—The two sexes are approximately equally affected. Acute lymphatic leukaemia is most common in the first 5 years of life, the incidence then falls and about age 20 reaches a uniform level comparable with that of the myeloid and monocytic forms. Acute myeloid and acute monocytic leukaemia are fairly evenly distributed over the decades.

Symptoms—The onset is usually abrupt and more than half the cases begin with symptoms regarded as a cold, influenza or bronchitis, it is only when the infection fails to respond to treatment and the patient remains prostrated that a more serious disease is suspected. Other early symptoms are ulcerative stomatitis or tonsillar enlargement with sore throat and some cases first come under the physician's care after a prolonged hæmorrhage from tonsillectomy, dental extraction or some trifling operation which has left the patient exsanguinated. The course of the disease varies from fulminating cases in which the patient succumbs within a week through cases of average acuteness with a duration of less than 2 months to subacute cases which shade indefinitely into chronic leukaemia. Usually the rapid development of anæmia, weakness and loss of weight soon compels the patient to take to his bed. He complains of sore throat, headache and pain in the bones. The temperature becomes high and purpuric manifestations set in which aggravate the anæmia or bring the patient's sufferings to an abrupt termination by loss of blood or cerebral hæmorrhage.

On examination the extreme pallor and the enlargement of the superficial lymph glands, especially those in the neck, first attract attention. The pallor is most striking when there are in addition purpuric hæmorrhages into the skin, varying in extent from a pinpoint to large patches which may break down and ulcerate. The size of the spleen varies, usually it is easily palpable but it may not be felt or it may be greatly enlarged. The liver may be enlarged. The lungs may show bronchitis.

broncho-pneumonia, or pleurisy, with or without effusion. Pericarditis and endocarditis may occur. The mind usually remains clear to the end. Certain symptoms may be so prominent as to colour the whole clinical picture and give a special aspect to the disease. In the unginal type, there is necrotic ulceration of the tonsils or other areas of the buccopharyngeal mucous membrane, or bleeding from the gums, complicated by secondary infection. In the hæmorrhagic type, purpura and hæmorrhages are the predominant features, and the disease may be mistaken for purpura hæmorrhagica. There may be hæmorrhage from any of the mucosæ, and in one of my cases there was so much blood in the urine that firm clots formed in both pelvis and ureters, leading to death from suppression of urine. Disturbances of vision or deafness may result from hæmorrhage into the retina or the labyrinth. The fever and slight splenomegaly may be suggestive of some systemic infection, and there may be leucopenia and an eruption resembling the rose spots of typhoid fever. Bone pains may suggest the diagnosis of acute rheumatism, and there may even be serous effusion into the joints.

In the more subacute forms of the disease, tumours may develop in various parts of the body. They are composed of undifferentiated white cells and infiltrate the surrounding tissues like a malignant growth. Plum coloured nodules appear in the skin or in the gastro intestinal tract, in the latter situation leading to vomiting or profuse diarrhoea, often blood stained in character, or to intussusception of the bowel. In the abdomen or in the mediastinum large growths may develop from the lymph nodes or the thymus, compressing and infiltrating the adjacent structures. Tumours of the bones have been distinguished by the special title of *chloroma*, owing to the greenish colour sometimes seen in the freshly cut surface of the growth. They have a predilection for the subperiosteum of the orbit, and cause headache, deformity of the temporal and frontal bones, exophthalmos, proptosis, papilloedema and swelling of the veins of the head, neck and face. They may, however, occur in other parts of the skeleton, and sometimes seem to arise within the bone which is expanded over them in a brittle shell. The spinal meninges may be invaded, with consequent transverse myelitis, while infiltration of the nerve roots leads to peripheral nerve palsies. It is a curious feature of these neoplastic phenomena that they often begin with a very atypical blood picture, the total white count not being greatly increased and in rare cases the differential count being normal at the onset, though the typical blood picture of leukaemia appears later.

Hæmatology and Pathology.—The outstanding feature of the blood in acute leukaemia is the presence of a large number of mononuclear cells of a primitive type, except in rare cases of acute lymphatic leukaemia, in which the predominant cells may be typical lymphocytes. The classification of the cells is not easy and sometimes they are too primitive to be identified. Figures for the incidence of the different types of acute leukaemia in recent series are 40 to 55 per cent. lymphatic, 25 to 33 per cent. myelogenous and 20 to 25 per cent. monocytic. The total white count is rarely high in the early stages of the disease, usually not exceeding 25 000 to 30 000 per c mm., but, as a rule, there is a rapid rise to 100 000 or more before the termination. Primitive cells constitute 90 per cent. or more of the white blood cells. Sometimes the total number of white cells is diminished and the count may be below 1000, the majority of the cells being myeloblasts. Such *leucopenic* cases are very prone to necrotic ulcerations and infectious complications. Much more rarely both the total and the differential white count are normal at the onset of the disease, as if the morbid process had not yet invaded the blood stream—*aleukæmic leukaemia*. The overgrowth of the primitive white cells in the marrow and the hæmorrhages soon lead to a profound anaemia usually of a normocytic type. The number of platelets is diminished in almost all cases, and sooner or later this is reflected in the hæmorrhagic character of the disease. The bleeding time is prolonged the tourniquet test is positive and the clot may not retract well.

The post-mortem findings vary only slightly from those of chronic leukaemia. There is diffuse hyperplasia of the leucopoietic tissues in the marrow, lymph glands and spleen, and all the tissues are infiltrated with myeloblasts, which may form nodules or tumour-like masses in various situations. Terminal hæmorrhagic and infectious lesions are rarely absent.

Diagnosis.—Acute leukaemia may simulate a number of diseases, among which may be mentioned the severe systemic infections, septic or diphtheritic inflammation of the mouth and throat, scurvy and the hæmorrhagic diseases, and malignant disease or tumours of bone. Usually the blood picture will be decisive, but the possibility of agranulocytosis or of septic infection should be remembered in cases in which only a few immature white cells are present in the blood. Glandular fever may cause confusion in the early stages, but the benign course and the absence of anæmia and hæmorrhages will soon differentiate it from leukaemia; in doubtful cases the heterophil antibody reaction, a serological test which is positive in glandular fever and negative in leukaemia, may be employed. The blood picture in acute leukaemia is sometimes suggestive of pernicious anæmia, but the other symptoms of that disease and its favourable response to liver are absent; examination of a bone-marrow smear obtained by sternal puncture is decisive.

Course and Prognosis.—Few diseases are more tragic than acute leukaemia, as it is invariably fatal and it so often affects lives which seemed full of promise. Onset at an early age, high fever and great immaturity of white cells, all point to a speedy fatal issue. Death often comes by intercurrent infection, especially in the leucopenic cases, or as a result of hæmorrhage. Rarely the disease may pass into a subacute or chronic form, and death be postponed for a year or longer. The average duration of life is about 6 months; in childhood about 50 per cent. die within 4 months and about 10 per cent. live for as long as 11 months. One of the most remarkable features of the disease is the occurrence of spontaneous remissions, often following some intercurrent infection. Remissions are described as complete, when both the clinical condition and the bone-marrow return to approximate normality, and partial, when the clinical condition is normal but the bone-marrow remains obviously abnormal. Remissions may last from a few weeks to a few months. The frequency of spontaneous remissions in the untreated disease is difficult to ascertain, but almost certainly less than 10 per cent. The aim of treatment is to provoke and maintain remissions.

Treatment.—The basic treatment of acute leukaemia consists of transfusion to relieve the anæmia and penicillin or other antibiotics to check infection. Exchange transfusions were used for a time, as they may initiate remissions, but it is now believed that the same effect may be produced with less disturbance of the patient by ordinary transfusions plus cortisone.

More active treatment raises difficult ethical questions and it should be made clear to the relations, before embarking on active treatment, that there is no question of cure but merely of a short prolongation of life and that the side-effects may be distressing. Active treatment may be of two kinds. The first is hormone therapy with corticotrophin or cortisone in doses sufficient to produce hypercortisonism. The second is chemotherapy with antagonists to folic acid or the purines. The chemicals most commonly used are aminopterin in a dosage of 0.5 to 1.0 mg. daily and amethopterin in a dosage of 3 to 5 mg. daily. Treatment is continued till either remission is produced or toxic symptoms appear; treatment is then suspended for the time or a maintenance dose may be determined. The folic-acid antagonists are extremely toxic and their use should be confined to the expert. Toxic effects may be partially reversed by the administration of folic acid.

With either form of therapy partial or complete remissions are obtained in rather less than half the cases in children; in adults remissions are rarely obtained. The best results are obtained in the lymphatic type, particularly the subacute leucopenic

form, acute myeloid leukaemia reacts in only a small proportion of cases and acute monocytic rarely if at all. The average duration of remissions is about $2\frac{1}{2}$ months. When relapse occurs, the attempt may be made to provoke a second remission with the same drug, or if this fails, to alternate chemotherapy and hormones. Sooner or later a cell population develops which is resistant to all forms of therapy and the patient dies. By active therapy the 12-months' survival rate has been raised from approximately 5 to 30 per cent. Radiotherapy is contraindicated in acute leukaemia, it aggravates the low neutrophil and platelet counts and does not produce a remission.

L. J. WITTS

BLOOD COAGULATION

When normal blood is shed, it forms a firm fibrin clot in 5 to 10 minutes. The appearance of this clot is the last stage in a series of reactions—the clotting mechanism—which has been the object of intensive research since 1905. It has given rise to a number of increasingly complex theories and hypotheses, as more and more phenomena occurring in the course of coagulation have been described, and often variable interpretations attached to them. The basic outlines of the coagulation mechanism are contained in the "classical" theory of Morawitz (1905), and are now generally accepted, but the important discoveries of more recent years, including anticoagulant drugs, have necessitated modifications of this simple scheme.

Blood clot results from the conversion of the globulin fibrinogen to fibrin by thrombin, a protein which can be obtained from plasma in fairly pure form. This reaction is probably enzymatic and may be due to the polymerisation of fibrinogen molecules. Thrombin is not naturally present in normal blood, and is formed quantitatively during the clotting process from its precursor, prothrombin. It is in the reactions involved in the conversion of prothrombin to thrombin that the most important new advances have been made, and this stage in the clotting mechanism is the important one in studying the actions of anticoagulant drugs, of the coumarin type.

It has long been known that calcium is necessary for blood coagulation, and that tissue extracts greatly accelerate the clotting of citrated or oxalated plasma in its presence—from a clotting time of several minutes to 15 seconds or less. Active extracts can be prepared from most tissues, notably brain, lung and placenta, and are called tissue thromboplastin. The basis of the classical theory (Morawitz) is that such thromboplastin converts prothrombin to thrombin in the presence of calcium. This tissue thromboplastin probably acts as a catalyst, and a constant constituent of it is a glycoprotein of high molecular weight.

It has long been known that platelets play some part in the initiation of clotting, and Quick (1947) and Brinkhouse (1947), working with hæmophilic plasma, suggested that a factor from platelets acted on antihæmophilic globulin, to form blood thromboplastin. That these two factors—platelet factor and antihæmophilic globulin—are necessary for the formation of thromboplastin in blood is now clear, but additional important clotting factors in plasma and serum have been described which modify and extend the classical theory, and throw much light on the problem of how blood itself may form a potent thromboplastin. Of these new factors, the two most important are generally called factor V and factor VII. Factor V is found in normal plasma, is very labile on storage, is not adsorbed by inorganic precipitates and disappears in the course of clotting, i.e. it is not found in normal serum. In its absence, the conversion of prothrombin to thrombin in the presence of tissue thromboplastin and calcium occurs more slowly than normally, and it has generally been regarded as an accelerator of prothrombin conversion. Factor VII, of greater importance in the study of anticoagulant drugs, is found in high concentration in normal serum, and is

probably formed from a precursor in the plasma by contact with a foreign surface, it is stable on storage, and is adsorbed by $\text{Al}(\text{OH})_3$, BaSO_4 and $\text{Ca}_3(\text{PO}_4)_2$, it increases the activity of brain thromboplastin, and, like factor V, has been regarded as an accelerator of prothrombin conversion to thrombin. Vitamin K is probably necessary for the formation of factor VII, and of prothrombin.

It is now known that under certain conditions, such as contact with a foreign surface, blood generates thromboplastin in which platelets and antihæmophilic globulin are constituents, and which converts prothrombin to thrombin in the presence of factor V, factor VII and calcium. Until 1953, the action of intrinsic blood thromboplastin was thought to be weak in view of the relatively long clotting time of normal whole blood or plasma compared with the greatly accelerated clotting time of plasma when tissue thromboplastin is added. It has now been shown by Biggs, Douglas and Macfarlane (1953) that a very potent thromboplastin is generated from a mixture of the above blood factors in optimal amounts, viz. platelet factor, antihæmophilic globulin, factor V, factor VII and calcium, together with another serum factor called Christmas factor (from the name of a family that lacked it) which in its chemical properties resembles factor VII and physiologically resembles antihæmophilic globulin. This blood thromboplastin can clot recalcified plasma in 10 to 15 seconds, i.e. it is as potent as any tissue thromboplastin, but its generation in the mixture of factors is delayed for 3 to 8 minutes, hence in all probability, the delay in the clotting time of normal blood. If any one or more of these factors is deficient, the thromboplastin generated is greatly reduced in quantity. Lack of antihæmophilic globulin delays thromboplastin generation, with consequent prolongation of the whole blood clotting time. Deficiency of the other factors, e.g. factor VII, can impair the process without affecting the clotting time, unless the deficiency is extreme.

It is now possible to draw up a more detailed scheme of the clotting mechanism, showing the generation of blood thromboplastin from its constituents, with the consequent conversion of prothrombin to thrombin. Thrombin, once formed, also accelerates the generation of blood thromboplastin. Tissue thromboplastin is equivalent in its action to a mixture of platelet factor, antihæmophilic globulin and Christmas factor. Factors V and VII, the accelerators of the action of tissue thromboplastin, are necessary constituents of blood thromboplastin. Accurate laboratory methods are available for the qualitative and quantitative determination of deficiencies in all these factors, and play a big part in the study of hæmorrhagic diseases and the action of anticoagulant drugs.

ACTION OF ANTICOAGULANTS OF THE COUMARIN TYPE ON BLOOD COAGULATION—The one stage "prothrombin" test (Quick) was based on the classical theory of Morawitz, the reaction taking 10 to 15 seconds and the end point being the formation of a fibrin clot. It was suggested that if all the other factors were present in optimum amounts the time taken to form a clot depended on the amount of prothrombin present. This test has proved valuable in clinical work and it is usual to keep the "prothrombin" time of plasma of patients under treatment with coumarin type anticoagulants at two to three times the control clotting time.

Recent work has shown that it is factor VII which is principally affected by the action of the coumarin type anticoagulants and the mode of action is by impairing blood thromboplastin generation. The concentration of prothrombin in the blood is also reduced by the drugs but only to 30 to 60 per cent of normal as measured by the two stage method of Biggs and Macfarlane. These amounts of prothrombin are perfectly adequate for normal blood coagulation, and it is therefore unlikely that anticoagulants produce their therapeutic benefit by this action. The one stage "prothrombin" test is a sensitive measure of factor VII concentration, and as factor VII reduction is responsible for the therapeutic effects of anticoagulants, the test remains satisfactory for routine clinical use.

R. B. HUNTER.

THE HÆMORRHAGIC DISEASES

A. DISTURBANCES OF BLOOD COAGULATION

The hæmorrhagic diseases may be arbitrarily classified into those which are due to defective coagulation of the blood, of which hæmophilia is the typical example, and those in which the blood clots normally, of which purpura is the typical example. Blood clots are dissolved by ferments known as fibrinolysins.

It is doubtful whether the clotting process is ever affected by shortage of calcium, as this would produce other serious manifestations first. Fibrinogen has to be reduced to a fifth of the normal value before effects on coagulation are seen. Deficiency of this degree is seen in the rare congenital disorder, *congenital afibrinogenæmia*. Acquired fibrinogen deficiency has been described as an acute phenomenon in childbirth and after the operation of lobectomy, it is attributed to sudden defibrination of the blood by the absorption of thromboplastic material into the circulation. A few cases of disturbance of coagulation by naturally occurring anticoagulants have been described. The only two important conditions in which coagulation is impaired are hæmophilia and hypoprothrombinæmia. In hæmophilia the blood clots normally on the addition of thromboplastin, the word hæmophilia should be strictly confined to hereditary hæmorrhagic disorders of this type and words like pseudo hæmophilia and para hæmophilia should be avoided. In hypoprothrombinæmia the blood does not coagulate normally even in the presence of an excess of thromboplastin.

1 HÆMOPHILIA

Definition—A hereditary disease of males, characterised by a tendency to uncontrollable hæmorrhage and a great prolongation of the coagulation time.

Ætiology—The disease is inherited by the law of Nasse, according to which it is transmitted only by females and manifested only by males. In Mendelian terminology it is a sex-linked recessive, theoretically it might be expected to occur in females in the proportion of 1 to 200 affected males, and in a small number of cases it has been convincingly demonstrated in females. True hæmophilia occurs sporadically in children without previous family history in about 25 to 30 per cent. of the total cases recorded. There is no reason to believe that the sporadic condition differs from the inherited. It is probably due to a mutation, so that either hæmophilic males or female transmitters may arise *de novo*. The latter is the commoner explanation and the mother of a boy with the sporadic form of hæmophilia should be warned that other sons will probably be affected. Hæmophilia is the commonest of the hereditary hæmorrhagic disorders, and its occurrence in the royal households of Europe has made it generally known.

Pathology—The disease is due to inadequate release of thromboplastin. In classical hæmophilia (Hæmophilia A or Hæmophilia I) this is due to deficiency of anti-hæmophilic globulin but a variant is now recognised (Hæmophilia B or Hæmophilia II) due to shortage of another factor in the plasma, which was called "Christmas factor" after the name of the patient in whom the condition was first diagnosed.

Symptoms—The disease usually manifests itself in early life, but not at birth so that there is no excessive hæmorrhage from the cord. Severe bleeding at circumcision is common, and in 60 to 70 per cent. of recorded cases the disease was recognised before the second year. It is doubtful whether the bleeding is ever spontaneous, and there is no purpura, but excessive hæmorrhage may occur from a mere scratch, and great bruises or ecchymoses from trivial injuries. Some patients cannot use a toothbrush on account of bleeding from the gums. Epistaxis is common, but internal bleeding is unusual, though hæmatuna, melæna and hæmatomyelia have been

described. Trauma and dental extraction are the most usual causes of severe hæmorrhage and a laceration of the muscles which would pass unnoticed in an ordinary boy may lead to an extensive intramuscular hæmorrhage which leaves the patient exsanguinated. The bleeding is not so much severe as persistent, hence it is rare for the hæmophilic to die of a sudden profuse hæmorrhage, he rather fades out of life owing to the inability to stop the slow continued loss of blood.

The most remarkable form of hæmorrhage, and one which is common, is into the cavities of the joints. The joints which suffer most often are the knees and elbows, but any joints may be affected. The swelling and effusion take place with great rapidity, and with a great deal of pain. The joint is hot, tender, reddened and the surrounding tissues swollen. The temperature is raised to 101° or 102° F. The effusion is almost pure blood, but as absorption proceeds it becomes a dirty brown colour, which stains the synovial membrane and the cartilages of the joint. It is sometimes absorbed rapidly, and the joint restored to complete mobility. When absorption is slow or effusions repeated contraction and ankylosis may cripple the patient permanently. In a joint often affected there is always considerable destruction of the cartilages and of the ligaments, with the result that the bones are exposed and undergo changes resembling those of osteo arthritis. Osteophyte formation is however, rare, and so is bony ankylosis. Fibrous ankylosis is, on the other hand common. The spleen is not palpable.

Diagnosis.—The diagnosis is based on the family history and on the delayed coagulation of the blood, the cytology and chemistry of the blood are normal. Special laboratory tests are available, such as the prothrombin consumption and the thromboplastin generation with which the diagnosis can be confirmed with practical certainty in cases of doubt. The joints are sometimes mistaken for tuberculous joints. A more serious error is to incise a hæmatoma on the mistaken diagnosis of an abscess. Hæmophilia should be differentiated from other hereditary hæmorrhagic states and from acquired conditions, such as essential thrombocytopenia.

Prognosis.—It is said that less than 12 per cent. of hæmophiliacs survive to puberty, but the disease undoubtedly becomes less severe in later life, though still present. A peculiar feature of the disease is its variability, the blood at times clotting almost normally, at other times seeming almost incoagulable, and if the patient survives a severe hæmorrhage there is often a temporary improvement in the blood.

Treatment.—Treatment is unsatisfactory, and it is much better to try to stamp out the disease by discouraging the reproduction of affected families. The only members of a hæmophilic family who can safely beget children are the unaffected males. Sufferers from the disease should be protected from trauma as far as possible, and operations should be discouraged unless they are essential to life. It is wise to admit the patient to hospital for minor operations, such as dental extraction, and not more than two or three teeth should be taken out at a time. If hæmorrhage from trauma or dental extractions persists, transfusion is the best general treatment. In local treatment a purified thrombin or snake venom may be used and it is now possible to repair wounds which would previously have been fatal. Purified thrombin can be applied either as a powder or in solution. It can also be used in conjunction with fibrinogen or fibrin, thus a bleeding tooth socket may be filled with fibrin foam which has been moistened with thrombin. The venom of Russell's viper (1 in 10,000 solution) or of the Australian tiger snake (1 in 5000 solution) has also been used. The loose clot is washed away from the bleeding point with hot water, and tampons or other appropriate dressings soaked in the venom solution are then applied. When cavities have to be packed, an absorbable material such as oxidised cellulose, may be used. Devitalisation of tissues by local anaesthetics, cauterisation or excessive pressure should be avoided. It is better for the patient to bleed externally than into the tissue planes. Threatened asphyxia from bleeding into the tongue or the tissues of the neck is not an uncommon accident and it is better treated by intubation than by tracheotomy.

2 HYPOPROTHROMBINÆMIA

The term hypoprothrombinæmia is now known to include not only conditions in which prothrombin is deficient but also conditions in which certain closely associated factors (Factor V and Factor VII) are deficient. Hypoprothrombinæmia is recognised by the fact that the blood does not coagulate normally even in the presence of an excess of thromboplastin. Prothrombin is formed in the liver under the influence of the fat soluble vitamin K. Prothrombin deficiency may therefore occur under the following circumstances

- (i) Deficient intake of vitamin K in states of extreme malnutrition
- (ii) Deficient absorption of vitamin K in intestinal diseases and in fatty diarrhoea as in obstructive jaundice, celiac disease and sprue
- (iii) Deficient utilisation of vitamin K when the liver parenchyma is diseased
- (iv) Depression of formation of prothrombin by the specific action of dicoumarol and similar anticoagulants
- (v) In the newborn (*melena neonatorum*) see below

Hypoprothrombinæmia can be prevented or treated by the administration of vitamin K, except in cases where the liver parenchyma is diseased. Failure to respond to treatment with vitamin K in a case of jaundice is a strong indication of hepatic damage. Transfusion is relatively ineffective in raising the level of prothrombin, even though large amounts of fresh blood or plasma are given. Vitamin K is commonly given in the form of one of the water soluble compounds such as menadione, Sodium Bisulphate (U.S.P.) or one of the similar proprietary preparations. Dosage varies with the particular preparation but is of the order of 5 to 30 mg daily. In over dosage with dicoumarol and similar drugs the water soluble preparations of vitamin K may have no effect and the patient should be treated with vitamin K₁ by mouth in a dosage of 10 to 50 mg which may be repeated at intervals of 4 to 6 hours if the prothrombin does not show a satisfactory increase.

3 MELÆNA NEONATORUM

Synonym—Hæmorrhagic Disease of the Newly born

Ætiology and Pathology—The blood is cytologically normal and the condition is essentially due to hypoprothrombinæmia. Both the bleeding time and the clotting time may be greatly prolonged. The incidence has been placed as high as 1 per cent of all births, male and female. Heredity seems to play no part. In some cases acute gastric and duodenal ulcers have been found at autopsy, but it is more probable that these represent necrosed areas from submucous hæmorrhages than that they are the cause of the bleeding.

Symptoms—The bleeding is spontaneous, commencing at any time in the first week or two of life, most commonly on the third or fourth day. The bowel is the usual site of hæmorrhage but blood may also ooze from the mouth, nose and urinary tract, or be extravasated into the viscera or the cavities of the body. If the disease is not immediately treated, death from hæmorrhage and shock soon occurs.

Diagnosis—This can be confirmed if necessary by estimating the prothrombin time. Hæmorrhagic states may occur in the newborn as a result of sepsis, syphilis, thrombocytopenia and other blood dyscrasias but all are rare.

Prognosis and Treatment—The prognosis depends on the promptitude of the treatment and the amount of blood already lost. Hæmorrhagic disease can be prevented by giving the mother 25 mg menaphthone or 50 mg acetomenaphthone at the beginning of labour, or by giving the baby 5 mg of menaphthone as soon as possible after birth. If the baby is not seen until the disease has developed, an immediate transfusion of fresh blood should be given or if this is difficult 10 to 15 ml

of fresh blood may be injected subcutaneously. Owing to the risk of sensitisation to the Rh factor, female children should be typed and given blood of the same group except in the direst emergency. At the same time 5 mg. menaphthone in oil may be injected intramuscularly or 2 mg. menaphthone sodium bisulphite subcutaneously. During treatment the infant is kept as quiet as possible and not lifted from the cot. He can be fed by a bottle or spoon with breast milk, or if necessary, with an artificial food.

B. PURPURA AND ALLIED DISORDERS

In the narrow sense purpura refers merely to the occurrence of bleeding in the skin in the form of petechiae, macules or larger areas. In the wider sense it connotes a group of diseases which are characterised not only by these cutaneous lesions but also by bleeding from the mucosae and internally. Purpura can be conveniently classified into thrombocytopenic and non-thrombocytopenic forms, but it should be noted that factors which reduce the platelet count commonly damage the capillary endothelium as well. Haemostasis appears normally to occur in two stages, first, contraction of the damaged vessel, and second, occlusion by thrombosis. In all the purpuras, whether thrombocytopenic or non-thrombocytopenic, the first stage of haemostasis appears to be at fault, the capillaries do not retract properly when they are injured and the bleeding time is prolonged. In haemophilia the second stage is at fault and though haemostasis begins normally, bleeding recurs after a short interval.

The blood platelets.—The platelets are the third formed element in the circulating blood. They are spherical or oval, non-nucleated disks, with an average diameter of 2 to 3 microns, and with a hyaline cytoplasm which contains numerous granules. The average number of platelets is from 250,000 to 450,000 per c.mm., but there are great variations in health and according to the method of estimation employed. The platelets are believed to be produced by the megakaryocytes in the bone-marrow, and after a life of a few days they are phagocytosed by the cells of the reticulo-endothelial system. Large numbers of platelets are present in the spleen, but it is not certain whether they are held there in reserve or in process of destruction. The platelets play an important part in the arrest of haemorrhage, sealing wounds in the endothelial lining of the vessels, promoting the coagulation of the blood and securing the firm adhesion of the clot. Purpuric symptoms commonly appear when the blood platelets fall below 40,000 per c.mm. The following signs may also be observed in thrombocytopenic purpura: 1. The platelets are very variable in size and shape, and giant platelets may be present. 2. The blood clots in the normal time, but the clot does not retract and express the serum as rapidly and completely as in health. 3. The bleeding-time is greatly increased. If the blood from a sharp prick in the finger is soaked off with a filter paper without pressure every 30 seconds, bleeding normally ceases in 1 to 2½ minutes, but if the platelets are defective it may be prolonged even to an hour or more. 4. The capillaries are more fragile than normal. The sphygmomanometer is applied to the upper arm and the pressure is maintained midway between the systolic and diastolic level for 5 minutes. When the platelets are defective, a coarse purpuric rash may appear on the lower arm.

An increased number of platelets or thrombocytosis occurs after haemorrhage, trauma, operation or childbirth and favours the development of thrombosis. There is a rare condition known as *essential thrombocythosis* or *idiopathic thrombocythemia* in which a haemorrhagic tendency is associated with enlargement of the liver and spleen and high platelet counts, often over 1 million per c.mm. This is a variant of the conditions previously referred to as non-leukæmic myeloid splenomegaly (p. 748). In rare cases, but more particularly in leukemia and allied conditions, the platelets may be normal in number but inadequate in function; the bleeding-time is prolonged, the clot retraction is poor and the prothrombin consumption is reduced. This is classified as thrombocytopathic purpura. In exceptional cases this may occur

as a hereditary abnormality, also known as *hereditary thrombasthenia* or *Glanzmann's disease*. It should be noted, however, that the majority of the hereditary purpuras are the result of a capillary defect and the platelets are normal.

The endothelium.—A hæmorrhagic tendency due to a pure endothelial lesion is characteristic of scurvy, in which the plasma and the platelets are normal but the fragility of the capillaries is much increased. The same is true of the purpura of old age and nervous purpuras, such as stigmatisation. When hæmorrhagic states are due to lesions of the capillaries, plasma may also pass through the endothelial lining, producing wheals, local œdema of the tissues and urticaria, and the purpuric areas may be elevated above the surrounding skin.

Symptomatic hæmorrhagic states.—In hospital practice purpura and allied states are about six times as common as coagulation defects. The majority of these purpuras are secondary to other diseases. Symptomatic thrombocytopenic purpura is commonly caused by infiltration, fibrosis or aplasia of the marrow. It therefore occurs in leukaemia and allied disorders, aplastic anæmia and secondary carcinoma of the bone-marrow. The platelets are likely to be depressed in any condition in which the spleen is enlarged, though the mechanism by which this "hypersplenism" works is not clear. Thrombocytopenic purpura may also occur in association with glandular fever and rubella. Symptomatic non-thrombocytopenic purpura is seen most commonly in the infectious diseases. Purpura and a hæmorrhagic tendency have been observed in infections with the pyogenic cocci, scarlatina, chicken-pox, diphtheria, the enteric fevers, typhus, malaria and gonococcal and meningococcal septicæmia. They are also seen in malignant endocarditis and in tuberculosis, especially the miliary form. In all such conditions we have reason to believe that the endothelial lining of the vessels is damaged. The platelet count is usually normal or slightly depressed. In rare cases it may be diminished, and the combination of thrombocytopenia and vascular damage produces a severe hæmorrhagic disorder which is known as *purpura fulminans*; this has been most commonly described after scarlet fever. Chronic nutritional disturbances and cachexias, such as uræmia and ulcerative colitis, may give rise to purpura and a hæmorrhagic tendency from vascular damage. Purpura of endothelial origin may also occur in conditions in which the plasma is unduly viscid and there is stasis in the peripheral vessels, as in hyperglobulinæmia from multiple myeloma and similar causes. Drug rashes not uncommonly take the form of non-thrombocytopenic purpura. After a number of organic and inorganic poisons, such as the sulphonamides, arsenicals and gold preparations, there may be both endothelial damage and thrombocytopenia.

The treatment of the symptomatic hæmorrhagic states is primarily the treatment of the underlying disease. The only reliable general remedy is the transfusion of fresh human blood. Liver, folic acid and cyanocobalamin are of value in the megaloblastic anæmias only, vitamin C in scurvy and vitamin K in prothrombin deficiency—they are not general hæmostatics. Vitamin P has little or no definable clinical action. For local treatment the measures advised for hæmophilia may be used.

1. IDIOPATHIC THROMBOCYTOPENIC PURPURA

Synonyms.—Essential Thrombocytopenia; Morbus Maculosus Hæmorrhagicus of Werlhof.

Definition.—A disease characterised by multiple hæmorrhages in the skin or from the mucous membranes, a reduced platelet count, a prolonged bleeding-time, but a normal coagulation time.

Ætiology.—Some 40 per cent. of the cases occur before puberty and at this age the sex incidence is equal. After puberty females preponderate in the proportion of approximately 3 to 1. Endocrine factors are also suggested by the exacerbation at menstruation and pregnancy and by the occasional association with thyrotoxicosis.

A few cases have been traced to idiosyncrasy for certain foods, such as milk, and for certain drugs, such as quinine or Sedormid. Ingestion of the offending food or drug is followed within a few hours by the onset of thrombocytopenia and purpura. Investigation of some of these cases has shown that the purpura is due to destruction of the platelets by an antibody reaction, in which the drug, complement and a fraction of the patient's plasma take part. Further investigation along these lines has revealed the presence of abnormal antibodies in the active stage of many cases of idiopathic thrombocytopenic purpura unconnected with drugs. These can be demonstrated by special tests for platelet agglutinins and in addition the Coombs test may be positive. Moreover, the plasma of a patient with idiopathic thrombocytopenic purpura may induce thrombocytopenia and purpura when injected into a normal individual. Finally, it may be noted that the child of a mother with idiopathic thrombocytopenic purpura may be born with thrombocytopenia and purpura which pass off in a few weeks. In thrombocytopenic purpura there appears to be a dual defect, firstly an abnormal vascular fragility and secondly an increased destruction of platelets. This dual defect may be explained by the antigenic similarity of the platelets and the capillary endothelium. As previously indicated, there is a link between idiopathic thrombocytopenic purpura and acquired hæmolytic anæmia (p. 747), and in rare cases thrombocytopenic purpura may be a manifestation of disseminated lupus erythematosus. It is appropriate here to mention the very rare syndrome of *thrombotic thrombocytopenic purpura*, in which thrombocytopenic purpura is associated with fever, hæmolytic anæmia and fluctuating neurological disturbances, and widely disseminated thrombi are found in the small vessels at necropsy; this syndrome, which has been fatal in all cases recorded, is likewise thought to be related to the collagen diseases.

A few cases of hereditary thrombocytopenic purpura affecting several children or several generations in one family have been described.

Pathology.—The bone-marrow usually contains rather more than its normal complement of megakaryoblasts and megakaryocytes and the younger forms predominate. The spleen shows no pathognomonic changes.

Symptoms.—It is customary to describe acute and chronic forms of the disease with the dividing line at 4 months, though this should not be regarded as a hard-and-fast division. The acute form begins suddenly and without warning, though sometimes there is a history of an acute infection a couple of weeks before. There is no pyrexia and the spleen is not palpable. Purpuric patches appear in the skin, of variable size and of irregular distribution. There is no erythema or whealing. Hæmorrhages occur from any of the mucosæ, the nose and mouth, the alimentary canal and the urogenital tract. The slightest injury gives rise to excessive bleeding or the formation of large hæmatomata. The bleeding time is greatly prolonged, and the tourniquet test is positive. Examination of the blood reveals a thrombocytopenia, platelets being perhaps completely absent; there is usually a slight leucocytosis, and immature red cells and even normoblasts may be poured out to combat the anæmia. In favourable cases recovery occurs in a few days or at most a few weeks, and the platelet count returns to normal. This may be the only attack, but in other patients a recurrence months or years later reveals that the disease is present in a relapsing form. In a second group the acute attack merely marks the onset of a chronic form of the disease and treatment by splenectomy ultimately becomes necessary.

The chronic form of the disease, which accounts for 2 out of every 3 cases in adults, may be of a continuous or a relapsing type. In the continuous type, which is the more common, there is persistent thrombocytopenia, with exacerbations of symptoms due to fluctuations of the platelets above and below the critical level of about 40,000 per c.mm., or to the effects of trauma or intercurrent infection. In the relapsing type there are long intervals of freedom during which the platelet count is quite normal. There may be persistent purpura, especially on the legs or the parts

exposed to trauma or purpura may be completely absent. The spleen may be slightly enlarged. There is a tendency for hæmorrhages to recur from the same site, as if it were an area of predilection, so that one patient may suffer from hæmatemesis, another from hæmaturia, another from menorrhagia.

Diagnosis—The diagnosis depends on the thrombocytopenia and the associated symptoms of platelet shortage, but it should be remembered that the platelets may be normal in the free intervals. The presence of any considerable degree of splenomegaly is a point against the diagnosis of essential thrombocytopenia. Many forms of symptomatic thrombocytopenic purpura are excluded by the examination of the peripheral blood. The marrow should be examined to confirm the diagnosis, and marrow puncture should be regarded as essential before beginning treatment with cortisone or splenectomy. Specific enquiry should be made for the taking of drugs likely to induce thrombocytopenia. Acute leukaemia is an important cause of purpura hæmorrhagica which should be excluded by the differential white blood count and, if necessary, the marrow smear. Henoch's purpura can commonly be distinguished at the bedside by the presence of toxæmia and joint pains and the characteristic appearance and distribution of the rash, further investigation shows that the platelet count is normal. In the chronic form of idiopathic thrombocytopenic purpura it is rather easy to overlook the possibility of a hæmorrhagic disease altogether, especially when there is no purpura and bleeding is always from one organ. On this account this diagnosis should always be considered in cases of symptomless hæmaturia or hæmatemesis or the like, or ill advised operations may be performed.

Prognosis—Death may occur in the acute attacks, or irretrievable damage be done, as by hæmorrhage into the vitreous humour of the eye or into the central nervous system. In childhood the disease is usually self limited and the mortality should not exceed 5 per cent. More than half of the children are better within a month and only in about 1 in 7 cases does the disease run on over 6 months. After puberty the outlook is less hopeful and spontaneous recovery is less frequent, but with modern methods of treatment the mortality should not exceed 15 per cent.

Treatment—In childhood and in mild cases in adults no treatment may be necessary. If the symptoms persist or are severe, an attempt should be made to provoke a remission with corticotrophin or cortisone. Large doses are desirable e.g. 300 mg of cortisone a day for 3 weeks in the adult. The hormones may act on the disease in two ways. They may diminish the abnormal fragility of the capillaries and they may increase the platelet count. Unfortunately in many cases they produce only the former of these effects: the platelets remain low and the remission is therefore only partial. No other drugs are known to have any effect on the disease and radiotherapy is of dubious value. The anaemia may require treatment by transfusion.

If the disease is chronic and a satisfactory remission cannot be provoked by cortisone splenectomy should be considered. Operation is rarely desirable in childhood as sooner or later nearly all cases remit and experience has shown that expectant treatment is justified. Operation is also rarely desirable in acute cases, where the symptoms should be controlled by cortisone and transfusions. Finally, splenectomy appears to be ineffective in the hereditary form of thrombocytopenic purpura. In chronic cases in adults operation should only be advised if the symptoms are really troublesome as an appreciable proportion of cases are not benefited by operation. A common indication for splenectomy is menorrhagia and operation should not be unduly postponed if the patient is being exsanguinated by the periods. The result of splenectomy cannot be predicted from the response to cortisone or the Coombs test but it appears likely to be successful in patients in whom platelet agglutinins are demonstrated.

Apart from cases with splenomegaly and hypersplenism which do not properly come into the category of idiopathic thrombocytopenic purpura the mode of action

of splenectomy is obscure. It removes an organ which may be producing abnormal antibodies and it protects the damaged platelets from the destructive action of the spleen. In addition it improves the capillary resistance, though this is probably the non-specific effect of any operation. The operation is usually followed by a great rise in the platelet count; this may be sustained, or it may subsequently fall to a sub-normal level without return of the purpura, or a frank relapse may occur. With proper selection of cases and preparation by transfusions and hormone therapy, the operative mortality should be negligible. There is little risk of interference with wound healing with ordinary therapeutic doses of cortisone. The immediate result is remission in about 85 per cent. of cases but permanent remissions are obtained in only about 66 per cent. Relapses after operation have been attributed to growth of a splenunculus but this is certainly not the only, or indeed the usual, cause. An aortogram may be taken to look for such a splenunculus. If severe menorrhagia persists after splenectomy, hysterectomy should be advised and at the same time a splenunculus should be sought for.

2. HENOC'S PURPURA

Synonyms.—Henoch-Schoenlein Syndrome; Anaphylactoid Purpura; Hemorrhagic Capillary Toxicosis.

Definition.—Although the term Henoch's purpura is sometimes restricted to cases characterised by purpura, colic and gastro-intestinal lesions, it is profitable to extend it to a group of non-thrombocytopenic purpuras, which are of obscure origin, and which may be accompanied by urticaria, oedema, swollen joints and various visceral manifestations. For this reason the milder cases which are known as purpura simplex, and also the peliosis rheumatica or arthritic purpura of Schoenlein are considered under this same heading, for all appear to be manifestations of the same pathological state.

Ætiology and Pathology.—The disease is related to allergic conditions, such as erythema multiforme, erythema nodosum, angioneurotic oedema and serum sickness. The lesions probably result from an abnormal permeability of the capillaries, which allow plasma and blood to escape through their walls. The sensitising agent is not always the same. In some instances it is the streptococcus, the attack following a sore throat, or persisting until a septic focus is drained. In other instances sensitisation to foods has been demonstrated, and the disease has been cured by removing them from the diet. Children and adolescents are chiefly affected, the incidence reaching a peak in the teens and falling off abruptly after 30. Seventy per cent. of the cases are males.

Symptoms.—The attack is usually preceded by symptoms of general bodily disturbance, such as headache, malaise, loss of appetite and a rise of temperature. In the mildest cases (purpura simplex) a fine purpuric eruption appears, often affecting the limbs rather symmetrically, and with a special tendency to develop round the hair follicles. In the typical Henoch-Schoenlein syndrome the first lesions are small urticæ, which later become dusky-red macules which do not fade on pressure. The lesions have a characteristic and symmetrical distribution—on the backs of the elbows, on the buttocks and lower back, and on the extensor surfaces of the lower legs, ankles and feet. Successive crops may appear. In severe cases there may be extensive, irregularly distributed ecchymoses, and there is much oedema of the face. Wheals and pemphigoid lesions may develop, and careful examination will often show that the purpura is not a pure hæmorrhage, but that it is raised or surrounded by a zone of erythema. Bleeding is not necessarily confined to the skin, but may be subperiosteal, intramuscular or intravisceral. Joint pains are rarely absent, though the joints are seldom much swollen, and there may also be myalgia or neuralgia. The gastro-intestinal symptoms take the form of colic, bilious vomiting and diarrhœa, with blood-

mixed stools. The abdominal wall may be rigid, and it may be difficult to differentiate the lesion from an intussusception, which may indeed occur from invagination of a piece of intestine whose walls have been stiffened by the exudation of serum and blood. Similar lesions occur in the urinary tract, but extensive hæmorrhage from the mucosæ is rare. The spleen may be palpable and the urine may contain albumin, blood cells and casts. In rare instances death has occurred from cerebral convulsions, suggestive of acute uræmia, nephritis is, indeed, the most important complication.

The blood is normal save for a slight anæmia or a mild leucocytosis. The platelets are normal or only slightly diminished, and the coagulation and bleeding times are normal. The tourniquet test may be positive, but in general there is little tendency to spontaneous or excessive external bleeding, and the mucosal hæmorrhages are small and attributable to oozing from areas of œdema and congestion.

Diagnosis—The disease is not sharply divided from the symptomatic purpuras. It should, however, be clearly differentiated from essential thrombocytopenia and similar blood disorders by the absence of specific changes in the blood, and the presence of signs of toxæmia and increased capillary permeability. Cases with intestinal lesions may closely simulate intussusception, and they may occasionally be complicated by intussusception or peritoneal effusion.

Prognosis—The prognosis depends almost entirely on the presence or absence of complications. Acute nephritis occurs in about 40 per cent of cases, it is usually a diffuse glomerulo nephritis and the prognosis is as for that condition. Gross alimentary lesions may give rise to intussusception or perforation. In patients admitted to hospital a mortality of 18 per cent has been recorded, but the general mortality is probably a good deal lower than this. Usually the disease tends to spontaneous recovery after an illness of a few weeks, though chronic and relapsing cases occur and can be very troublesome. Exceptionally the disease may persist for 2 to 4 years.

Treatment—There is no specific treatment. Corticotrophin and cortisone have proved disappointing and there is no evidence that they modify the course of the illness. Salicylates are likewise disappointing. A short course of penicillin may be given in cases following a throat infection. Nephritis should be treated on the usual lines. Abdominal exploration may sometimes be necessary, but in view of the relapsing nature of the disease it should be avoided if possible.

3 HEREDITARY HÆMORRHAGIC TELANGIECTASIA

Synonyms—Hamangiomatosis, Osler Weber Disease.

Definition—A hereditary disease characterised by multiple telangiectases, which cause hæmorrhages from various sources, especially the nose.

Ætiology—The disease is a hereditary dystrophy of the capillary system, which is transmitted directly from generation to generation affecting both sexes equally and behaving as a Mendelian dominant. As in hæmophilia, there is a small proportion of sporadic cases without a family history of the disease.

Symptoms—Epistaxis generally begins in childhood and before any cutaneous telangiectases have been recognised, but it tends to become more frequent and severe with advancing years. The telangiectases are not present at birth, and are sometimes not noticed till middle life. They vary in kind, appearing as dilated venules, spider capillary networks, punctate red or purple spots and blebs, and raised nævi up to an inch in diameter. They are most common about the face, nose and mouth, and the trunk and limbs are generally spared except for the tips of the fingers. Epistaxis is the common complaint, but external bleeding, hæmoptysis, gastrostaxis, hæmaturia or cerebral hæmorrhage may occur. The blood is normal, except for the anæmia induced by the bleeding.

Diagnosis.—This depends on the family history and the presence of telangiectases, and both these may be missed if they are not sought for. Few telangiectases may be visible, and epistaxis or alimentary hæmorrhage may be the presenting symptom. Many cases are first seen by the rhinologist.

Prognosis and Treatment.—There is no curative treatment, and death from hæmorrhage occurs in a considerable percentage of the cases. Affected members of these families should, therefore, be strongly advised against having children, as half of their offspring will inherit the disease. Treatment of the nævi by cauterisation or radium is only moderately successful.

4. HEREDITARY CAPILLARY FRAGILITY

Synonym.—Von Willebrand's Disease.

Definition.—A hereditary disease characterised clinically by an abnormal tendency to bruising and bleeding and pathologically by abnormalities in the morphology and function of the capillaries.

Description.—In our experience 60 per cent. of the hereditary hæmorrhagic disorders are accounted for by hæmophilia, 25 per cent. by hereditary capillary fragility and 15 per cent. by hereditary hæmorrhagic telangiectasia; all other forms are extremely rare. Hereditary capillary fragility and hereditary hæmorrhagic telangiectasia can probably be regarded as related genetic defects. In hereditary capillary fragility the tendency to bleed appears in childhood and there may be bleeding from the cord at birth. Bruising, epistaxis, bleeding from the gums and gastro-intestinal bleeding occur and there may be prolonged bleeding after injuries and operations. In women menorrhagia may be the most serious symptom. Petechiæ and ecchymosis may occur but purpura is not very common.

There is a positive family history in over 80 per cent. of reported cases. The sexes are equally affected. In most of the families inheritance is of the simple dominant type and the affected members may pass the condition to their children. The essential abnormal finding on investigation is the prolonged bleeding time. The platelets and the coagulation time are normal. The capillaries may be seen to be abnormal in shape and reaction if they are examined under the capillary microscope. There is no specific treatment though loss of blood may require treatment by transfusion. Splenectomy is useless and dangerous.

L. J. WITTS.

SECTION X

DISEASES OF THE SPLEEN AND THE RETICULO-ENDOTHELIAL SYSTEM

INTRODUCTION

THE spleen is not essential to life since the tissues found in it are also present in other parts of the body. It is, however, important because it contains the largest single mass of lymphatic tissue in the body which is concerned with the filtration of blood, and also because it is the main site of the reticulo-endothelial system. There are a few diseases which are confined to the spleen, but the vast majority which affect it, involve, in addition, other organs. Many of these, *e.g.* diseases of the blood, are fully described in their clinical aspects elsewhere in this volume.

The spleen is a soft reddish-purple organ that shows considerable variation in size although it usually has a length of about 5 in. It has a well-marked hilum through which the main vessels pass. It lies in close relation to the diaphragm, kidney, stomach and left colic flexure and is opposite the ninth, tenth and eleventh ribs behind the mid-axillary line. The spleen moves downwards about 2 in. on deep inspiration but is normally not palpable below the costal margin. When it enlarges it moves downwards and forwards towards the right iliac fossa.

In order to understand some of the difficult and, in many ways, still anomalous diseases of the spleen, it is necessary to consider briefly the structure and functions of the organ. An important general point to realise is that the spleen is made up essentially of lobes, not recognisable in the complex mammalian organ but clearly defined and with a separate end-artery in some lower animals. This lobularity explains abnormalities such as spleniculi (*q.v.*) which are simply isolated lobes or groups of them.

The tissues which make up the spleen are the capsule and trabeculae, the vascular structure, reticulo-endothelial and lymphoid tissues and the haemopoietic or blood-forming tissues.

THE CAPSULE.—This differs from that of a lymph node in that it contains numerous elastic fibres and a few muscle fibres. It is distensible and slightly contractile.

THE TRABECULAE.—These invade the splenic pulp from the hilum and the capsule and possess both elastic and a few muscle fibres.

THE SPLENIC LOBULE.—This is difficult to define in man. At the core of the lobule is the central artery which reaches it from the trabeculae. This artery runs in a Malpighian body, some capillaries nourish the Malpighian body—lymphoid tissue—while arterioles extend into the surrounding tissues—red pulp. Before they branch in the pulp their walls thicken and they are then termed sheathed arterioles. These are thickenings of reticulo-endothelial tissues. Thereafter as capillaries the vessels pass into the surrounding venous sinuses. The venous sinuses are drained by the trabecular veins, and the principal trabecular vein drains the lobule.

CIRCULATION IN THE SPLEEN.—The exact manner in which the blood circulates in the red pulp is not known with certainty. Some think the endothelial walls of the capillaries are incomplete. Others are of the opinion that they are complete but cells easily pass through the wall. Recent animal studies give a description of the passage of blood through the red pulp and of its filtration by the venous sinuses. Between the Malpighian body and the main trabecular vein draining the lobule there are two groups of sphincters, an afferent group at the sheathed arterioles and at the beginning of the capillaries, and an efferent group in the venous sinuses. If all sphincters are

open whole blood will pass through and the trabecular veins draining the blood sinuses may pulsate like arterioles. If the efferent sphincter is closed, blood flows in and the blood sinuses fill. As the blood fluid is absorbed by the walls the sinus becomes packed with blood cells. This is called filtration filling. A third phase begins with closure of the afferent sphincters. The blood cells contained in the sinuses are then shut off from the blood-stream. Storage may last from a few minutes to several hours. Cells may pass through the walls of the sinuses into the pulp during phase two or phase three. The last phase is emptying, the sphincters suddenly open and masses of blood cells enter the general circulation via the portal vein. There is such a great species difference that this may not be the mode of circulation in man.

THE SPLEEN AS A BLOOD RESERVOIR.—It has been conclusively shown that in animals such as the horse, the spleen is an important blood reservoir, but there is no evidence for such a function in man. True, subcutaneous injection of 1 mg. of adrenaline causes a reduction in size of the human spleen and discharge of some of its fluid contents into the circulation; at the same time there is a rise in the red cell content of the peripheral blood. This effect is due to arteriolar constriction. Such an increase of hæmoglobin and red cells also occurs in the splenectomised person and is due simply to a redistribution of red cells and plasma which increases the proportion of cells in the peripheral blood.

RETICULO-ENDOTHELIAL TISSUE.—The cells of this tissue are found in the framework of the red pulp, the endothelial cells of the sinuses together with those cells which form the mesh-like stroma and the lymph sinuses of the follicles. They are found also in the liver (Kupffer cells), bone marrow and in the lymphatic glands.

THE SPLEEN AS PART OF THE RETICULO-ENDOTHELIAL SYSTEM.—The main functions of the spleen as part of the reticulo-endothelial system are:

(a) *Phagocytosis.*—This is most active and results in the destruction of bacteria, protozoa and red blood corpuscles. This "filtering out" activity at once brings to mind the splenic changes in infections (typhoid fever, malaria) and the enlargement of the organ in hæmolytic anæmias (pernicious anæmia, acholuric jaundice).

(b) *Storage.*—The cells of the reticulo-endothelial system play an important part in the intermediary metabolism and storage of lipids, hæmoglobin and iron. These functions are referred to in detail in connection with Gaucher's and other diseases.

(c) *Immunity reactions.*—Much work has been done suggesting that the reticulo-endothelial cells of the body are the main source of antibodies, antitoxins, precipitins and agglutinins. It is certain that in chronic infective diseases these cells proliferate. Some hitherto unexplainable examples of splenomegaly (reticulo-endotheliosis of the spleen) may come into this category.

THE HÆMOPOIETIC OR BLOOD-FORMING TISSUES.—Monocytes are produced and enter the blood-stream. The normal adult spleen has lost its embryonic power of producing erythroblasts and myelocytes. In certain circumstances, however, the spleen can regain its erythropoietic power, particularly in diseases where the medullary spaces of the bones are decreased in size as in osteosclerosis, in severe hæmolytic anæmia, and occasionally in infectious diseases.

LYMPHATIC TISSUES.—Histologically the Malpighian bodies resemble lymphatic nodes but, as explained above, their vascular and lymphatic connections are by no means the same.

DISEASES OF THE SPLEEN

ABNORMALITIES OF THE SPLEEN

The spleen may be completely absent, or may take the form of small spleniculi (synonyms—splenunculi, accessory spleens), scattered throughout the upper abdomen,

A few small accessory spleens, in close proximity to an otherwise normal spleen, are quite common, and are involved in all the pathological processes of the main organ. Congenital lobulation is occasionally found, and demonstrates the essential lobular structure. Normally only the characteristic notch or notches on the anterior border persist as evidence of this fact.

FLOATING OR DISLOCATED SPLEEN

Rarely, because the splenic ligaments are lax and longer than usual, an otherwise normal spleen may be easily palpated on abdominal examination.

RUPTURE OF THE SPLEEN

Ætiology.—Rupture of the spleen may occur in the healthy person following injury. The injury need not necessarily be violent but is always sudden. The diagnosis may be particularly difficult in children when the injury may not be followed immediately by signs of shock. Spontaneous rupture may take place in chronic infections such as malaria where the spleen is much enlarged, in acute infectious diseases such as typhoid and diseases of the spleen or blood-forming tissues where there is gross splenomegaly. In all these conditions the spleen capsule has lost its elasticity and any sudden distension, rapid enlargement, or rough handling on physical examination may result in rupture of the capsule. Trauma sufficient to produce rupture may be so slight as to escape notice.

Pathology.—The tears in the splenic capsule may be longitudinal, transverse, single or multiple. In traumatic rupture of the healthy spleen they are almost always multiple. Usually both the capsule and the splenic tissue are torn.

Clinical Features.—Immediately following injury physical signs may be absent or symptoms and signs of blood loss may be present associated with pain in the left hypochondrium. Pain in the left shoulder may be complained of or may be produced by pressure to the left hypochondrium or by raising the intra-abdominal pressure as a whole. Even in the absence of signs of blood loss this is an indication for abdominal exploration.

Prognosis.—In the healthy person with traumatic rupture of the spleen the prognosis is good if efficient blood transfusion and surgical treatment is readily available. In pathological states the outlook is serious, particularly in acute infectious diseases.

Treatment.—This is surgical.

INFARCTION OF THE SPLEEN

Partial infarction or multiple infarctions, both aseptic and septic, are common in a great variety of diseases. They are usually of little clinical importance and do not require treatment unless there is pain due to pensplenitis. The commonest cause of abscess of the spleen is septic infarction. Surgical intervention is indicated when an abscess bursts giving rise to a generalised peritonitis.

CYSTS OF THE SPLEEN

Three varieties of cysts of the spleen have been described, namely, dermoid, echinococcus (hydatid) and serous or hæmorrhagic. All are uncommon. Only serous or hæmorrhagic cysts will be discussed.

Ætiology.—It has been claimed that this variety of cyst is congenital, and also that it may follow injury. Whatever the origin when once formed, it continues to grow slowly

Pathology.—Serous or hemorrhagic cysts may be single or multiple. They contain a mixture of fluid and light chocolate-coloured debris, with abundant cholesterol crystals producing a distinct sheen. Perisplenitis is common, but rupture is rare. A cyst may be deep within the splenic tissues.

Symptoms.—The cysts may be large enough to bring about considerable enlargement of the organ. A thinned out but apparently normal anterior margin, with the characteristic notch, may be felt through the abdominal wall and may cause confusion with other forms of splenomegaly.

The only pathognomonic sign is fluctuation, but even this can be given by a congenital cystic kidney. Repeated attacks of acute perisplenitis are a noteworthy feature.

Treatment.—Splenectomy should be performed as early as possible, before dense perisplenic adhesions have formed.

PERISPLENITIS

Perisplenitis, or inflammation of the splenic capsule, is encountered in a great many acute and chronic diseases, and is of considerable clinical importance. When acute, it is usually painful. Perisplenitis may be detected by manual palpation or frequently only by auscultation over the tender area. Acute perisplenitis may be of diagnostic importance, while in the chronic stages it may present a serious problem to the surgeon and hinder or prevent successful splenectomy, especially if there are dense adhesions between the upper pole of the spleen and the vault of the diaphragm. Perisplenitis over the anterior surface of the spleen, even when of long duration seldom gives rise to adhesions.

SPLENIC ENLARGEMENT

The spleen is enlarged in many infectious diseases (e.g. typhoid, typhus, bacterial endocarditis, abortus fever) and as far as the acute specific fevers are concerned the finding may be important only as an aid to the diagnosis of the particular infection. Splenic enlargement may be of considerable diagnostic importance in bacterial endocarditis, in amyloid disease, in miliary tuberculosis, sarcoidosis, in blood diseases such as leukaemia, in the reticuloses, portal hypertension and in tropical diseases such as kala azar and malaria.

In the recognition of slight splenic enlargement percussion is of little value and it is best to palpate the tip of the organ below the ribs with the patient lying on his right side.

An enlarged spleen may be difficult to distinguish from (1) tumours, enlargement and displacements of the left kidney, (2) a greatly enlarged left lobe of the liver, (3) carcinoma of the splenic flexure of the colon, (4) carcinoma of the body of the stomach, (5) a mass of carcinomatous or tuberculous tissue in the omentum. If these can be excluded a mass in the left upper abdomen is almost certainly an enlarged spleen. The splenic notch can usually be detected when the enlargement is generalised.

TUMOURS OF THE SPLEEN

Simple tumours are very rare, but fibromas, hæmangiomas and lymphangiomas have been noted.

Sarcoma is the only primary malignant tumour. Primary carcinoma of the spleen,

because of the absence of epithelial tissue, cannot exist, and even secondary carcinoma is rare.

Sarcoma is of two types—one diffuse and the other arising in, and producing great enlargement of, the Malpighian bodies. There may be great difficulty in deciding whether true tumour growth exists, or merely excessive proliferation of reticulo-endothelial cells. Secondary nodules in lymphatic glands may afford the only proof. Diagnosis is impossible without laparotomy. Splenectomy should be carried out, and cases of permanent cure are on record.

HYPERSPLENISM

This is not a disease *sui generis* but is a syndrome. It occurs in a variety of diseases involving the spleen—non-inflammatory, *e.g.* hæmolytic anæmias; inflammatory, *e.g.* chronic malaria; neoplastic, *e.g.* lymphosarcoma and Hodgkin's disease.

Clinical Features.—There is always some degree of hypochromic or normochromic anemia, marked granulopenia and sometimes thrombocytopenia. Sternal marrow biopsy reveals a hyperactive marrow and delayed cellular maturation. Three possible causes of this condition have been suggested. (i) Increased destruction of cells in the enlarged spleen. (ii) Endocrine inhibition of the marrow (splenic in origin). (iii) Excessive lymphocytopoiesis in the enlarged spleen with consequent disturbance between the lymphatic and myeloid systems. It is possible that all three factors are concerned.

Treatment.—Treatment of an infective condition, *e.g.* malaria or syphilis may cure the syndrome. Irradiation should be considered in neoplastic diseases. In other cases splenectomy should be considered.

THROMBOSIS OF THE SPLENIC VEIN

The sudden onset of thrombosis of the splenic vein gives rise to great congestion and enlargement of the spleen and the flow of blood in the gastric veins may be reversed with resultant engorgement and danger of severe and repeated gastric hæmorrhage. Abdominal pain and collapse may precede a fatal gastric hæmorrhage.

Partial or incomplete obstruction will be dealt with under congestive splenomegaly together with portal vein obstruction.

Diagnosis.—This is difficult. The signs are those of an intra-abdominal hæmorrhage.

Treatment.—Removal of the spleen by prompt surgical intervention is the only possible treatment.

BANTI'S SYNDROME

Synonyms.—Congestive Splenomegaly; Hepato-lenal Fibrosis.

Definition.—The syndrome consists of congestive splenomegaly, hypochromic anemia, leucopenia, thrombocytopenia and a history of attacks of gastro-intestinal bleeding or demonstrable evidence of the presence of œsophageal varices. The terminal stage is associated with hepatic cirrhosis, jaundice and ascites.

Ætiology.—Originally described as "anæmia splenica", 1866, and as splenic pseudo-leukæmia before the pathology of the leukæmias was understood, the name splenic anemia was again brought into clinical use by Osler in 1902. In recent years the syndrome of portal hypertension has been described, and its clinical features are indistinguishable from those of Banti's syndrome. The synonym, hepato-lenal

fibrosis, indicates the gross pathological changes. The presence of œsophageal varices indicates portal hypertension which is present at some stage of the disease. Disagreement exists as to whether this is primary, *i.e.* the cause of the condition, or secondary, *i.e.* occurring late in the disease as the result of the liver changes which are indistinguishable from cirrhosis. The thesis that all cases are produced by hypertension resultant from changes in the portal venous system is not accepted by all authorities. In favour of the view that the disease is a separate entity of unknown ætiology is the absence in some cases of demonstrable portal block and of œsophageal varices. When portal block with subsequent hypertension is present the cases may be divided into two groups depending on the site of the obstruction, (1) intra-hepatic and (2) extra-hepatic where the block is in the portal vein or the splenic vein. The second group make up 30 per cent. of the cases and the block is most often in the portal vein itself.

Pathology.—The characteristic histological changes in the spleen may be briefly summed up as peri-arterial hæmorrhages (some of which may develop into fibro-siderotic nodules); dilatation of the blood sinuses; proliferation of histiocytic (reticulo-endothelial) cells around the sinuses and in the pulp; and generalised fibrosis of the trabeculæ and reticulum. The Malpighian bodies also share in the fibrosis. The liver changes vary greatly in degree; in early cases biopsy and liver function tests may be normal, but the later stages differ in no way from those of ordinary hepatic cirrhosis. There are no other primary pathological changes of importance. The dilatation of the venous sinuses is evidence of venous congestion. It has proved possible in animals to produce congestive splenomegaly, thickening of trabeculæ and reticulum and hæmorrhages with fibro-siderotic nodules by the maintenance of portal hypertension. These changes in animals and the dilated collateral channels and the frequent severe hæmorrhages in man are conclusive evidence of a hæmodynamic component.

Symptoms.—*Splenomegaly* is inevitable but its degree varies. The average weight in a series of cases was about 900 g., but in extreme cases it may be as much as 3000 g. The spleen feels smooth, and is of firm consistence. Moderate anæmia is the rule unless the case is complicated by recent hæmorrhage. The bone marrow is normal or hyperplastic and the blood findings may be those characteristic of hyper-splenism, *i.e.* a leucopenia is present in association with a normochromic or hypochromic anæmia. Thrombocytopenia is unusual.

Hæmorrhage into the stomach, derived from large veins in the gastro-splenic omentum (*vasa brevia*) or from œsophageal varices occurs in a large number of cases and may be severe and repeated. The patient who escapes the hazard of gastric hæmorrhage dies from hepatic failure with portal obstruction, ascites and jaundice.

Course.—This is chronic, the duration varying from several to many years and in the majority 5 to 15 years.

Diagnosis.—The diagnosis is made by a process of exclusion after considering other forms of chronic splenomegaly.

Treatment.—This may be considered under two headings, surgical and medical. Surgical treatment is most urgently required to prevent or at least to reduce the risk of further hæmatemeses. Ligation of the splenic artery is useless, since more than 30 per cent. of cases have further severe hæmatemeses. Splenectomy should be reserved for those cases where thrombocytopenia is present or when the block is in the splenic vein. Ligation of the hepatic artery has been tried in selected cases. Operations to reduce blood flow through œsophageal varices are disappointing and the result in any particular case unpredictable.

The best way to reduce an increased portal pressure is to establish a porto-caval shunt. This operative procedure appears to protect many patients from œsophageal hæmorrhage. The operation should not be carried out where there is evidence of extensive liver damage.

Medical treatment—In the early stages of the disease when the patient's general health is good the anæmia which results from alimentary bleeding responds satisfactorily to the administration of iron. Later, when cirrhosis of the liver and its sequelæ are present, the response is not so satisfactory. If profuse bleeding occurs from œsophageal varices blood transfusion is urgently needed. Many patients have survived numerous hemorrhages with the aid of transfusion.

The diet should be bland and non-irritating to avoid trauma to the œsophageal varices and to the stomach. For treatment of cirrhosis of the liver, see p. 679.

DISEASES OF THE RETICULO-ENDOTHELIAL SYSTEM

Two prominent sites of reticulo endothelial cells in the body have been referred to under Diseases of the Spleen (p. 778) and Lymphatic System (p. 787). Two other important sites are the bone marrow and the liver (Kupffer cells). Diseases affecting these cells have been loosely grouped under the term "Reticuloses". Some histopathologists have confined the term to irreversible atypical and systematised proliferation of the particular cells of the system. Others use the term to include the primary neoplasms, benign and malignant, of the reticulo endothelial system. As an ætiological classification is not yet possible, considerable confusion exists and this is intensified by the difficulty of interpreting the histological changes.

Of the diseases variously classified as *reticuloses* only those associated with the deposition of lipid in the cells will be considered here. *Leukæmias* are dealt with in the section on Blood Diseases, p. 757, and *Hodgkin's disease* under Diseases of the Lymphatic System, p. 789.

LIPOID DEPOSIT DISEASES

HAND-SCHULLER-CHRISTIAN'S DISEASE

Synonyms—*Normocholesterolæmic Xanthomatosis*, *Eosinophilic Granuloma*.

Hand, 1893, Schüller, 1915, and Christian, 1919, have all drawn attention to a clinical syndrome, limited to children, of defects in the membranous bones, exophthalmos and diabetes insipidus. Rowland, 1928, demonstrated the identical character of the pathological changes present in the granulomatous lesions of bone, brain and lung.

Ætiology—The fundamental abnormality of this disease is still quite unknown, but although the cholesterol content of the xanthomatous lesions is as high as is found in the lesions of hypercholesterolæmic and hyperlipæmic xanthomatosis, the serum of patients with this condition is normal in its cholesterol phospholipid and neutral fat content. Blood chemistry studies have differentiated this condition from hypercholesterolæmic and hyperlipæmic xanthomatosis though all these conditions may show xanthomatous skin lesions.

Pathology—The lesions are granulomatous in character, consisting of reticulum cells and histiocytes, cholesterol containing foam cells and eosinophils, red cells and polynuclear elements.

There are roughly four phases of development of the lesions—(1) reticulo histiocyte proliferation, (2) granulomatous phase with increase of blood vessels and fibrils, reticular cells, histiocytes, eosinophils, giant cells and incipient lipid accumulations, (3) xanthomatous phase containing foam cells, (4) a fibrous stage considered to be a healing phase.

Letterer Siwe's disease is considered to be an acute early phase of the same condition which has not progressed to the stage of lipid storage

Clinical Features—The syndrome occurs mainly in children and infants adult cases are rare It may be complete with bony changes exophthalmos diabetes insipidus lung lesions and associated xanthoma disseminata or any case may present one or more of these features In these circumstances diagnosis may only be established by biopsy The commonest non symptomatic type is the solitary eosinophilic granuloma of bone Diabetes insipidus and xanthoma disseminata may occur without lung or bone involvement Xanthoma disseminata has to be distinguished from juvenile benign xanthoma which is an innocent lesion Even in the fully developed picture enlargement of the spleen and liver is rare

Prognosis—When the disease appears in early life it is rapidly fatal whereas an onset in adolescence or adult life may mean many years survival

Treatment—Dietetic restrictions are valueless Radiotherapy will often lead to disappearance of local lesions The diabetes insipidus responds to the usual therapy for that disease (p 490)

HYPERCHOLESTEROLÆMIC XANTHOMATOSIS

This condition is familial unlike the normocholesterolæmic type (Hand Schüller Christian's disease) which never runs in families Xanthomatous deposits occur around tendons in the eyelids or the blood vessels (atheroma) but other members of the family may show equally high serum cholesterol values without any evidence of local deposits

Pathology—The histology differs from the normocholesterolæmic type Xanthoma cells (foam cells) are found at all stages of the disease The lesions may soften and cholesterol crystals appear in the tissue spaces

Clinical Features—Tuberous xanthomata are found as nodular elevations of the skin but not on the mucous membranes They occur as isolated lesions or in small groups with a brownish yellow discoloration The serum cholesterol levels are high

Prognosis—The cases show a remarkably high incidence of myocardial infarction in early life

Treatment—Diets low in cholesterol content are advised

HYPERLIPÆMIC XANTHOMATOSIS

Hepato-splenomegaly and secondary xanthomatosis result from hyperlipæmia with excessive phagocytosis by the reticulo endothelial system and production of foam cells The condition is rare The reason it is mentioned is that dietary treatment with restriction of fat is said to produce considerable improvement in this condition Such treatment is of no value in hypercholesterolæmic xanthomatosis When hyperlipæmia is associated with diabetes mellitus treatment of the latter condition will reduce the degree of the lipæmia

GAUCHER'S DISEASE

Synonym—Lipoid Storage Spleno hepatomegaly

Definition—A rare familial constitutional disorder of the cellular metabolism in the reticulo endothelial cells Reticulum cells and histiocytes become enlarged and filled with a lipid substance named *ceramide* This leads to an enlargement of the spleen and liver and deposits in bone marrow and lymph nodes

Ætiology.—The disease is a disorder of lipid metabolism but whether it is an upset of the intermediate metabolism of lipoids or a metabolic disorder involving only certain cells in the affected organs is unknown. Plasma lipoids are normal. The disease begins insidiously in early life, most cases being recognised before 10 years of age. Several members of a family may suffer from the disease. It is commoner in females and many of the cases are of the Jewish race.

Pathology.—The characteristic feature of the disease is the large pale striated Gaucher cell containing glucosido cerebrosides (kerasin) and the spleen, liver, lymph nodes and bone marrow are packed with such cells. They are the immediate cause of the enlargement of the organs. In the later stages of the disease there is marked increase in the connective tissue of the liver and spleen.

Symptoms.—Slowly progressive splenic enlargement is the first sign. The spleen may become enormous. This is followed later by the enlargement of the liver, and to a lesser degree of the lymph glands. Skeletal changes with spontaneous fracture may occur, caused by destructive infiltration from the bone marrow. The skin of the face, neck, forearms and hands frequently shows a brownish yellow pigmentation, and it is less commonly seen on the legs. It has nothing to do with exposure to light. The eyes show a phenomenon which is so constant as to be almost pathognomonic. A brownish yellow wedge shaped thickening or pinguecula appears in the bulbar conjunctiva near the cornea, first on the nasal and later on the temporal side, of each eye. Hemorrhages from mucous membranes are common and are associated with thrombocytopenia. There are no characteristic changes in the white cells of the blood but leucopenia is frequent. Anæmia occurs late in the disease.

Course and Prognosis.—There is an acute infantile form of the disease which starts in the first 6 months of life. Death usually results in the second year. The chronic form begins in the first 10 years of life and exhibits a slow progressive advance. Cases are on record of over 40 years' duration, and of 20 years after splenectomy in adult life. Death often ensues from some intercurrent disease.

Diagnosis.—The familial history, early onset, great and progressive spleno-megaly, hepatic enlargement, changes in the eyes, and dermal pigmentation constitute an almost unmistakable picture. Sternal marrow biopsy confirms the diagnosis, the characteristic large pale striated cells being sometimes recognisable in the films and, more frequently, in sections made from the fragments. Glycogen disease (p. 452) is distinguished clinically by the great hepatic enlargement, without accompanying splenomegaly.

NIEMANN-PICK'S DISEASE

Synonym.—Phosphatide Lipoidosis

Definition.—A very rare familial constitutional disorder of cellular metabolism of reticular and histiocytic cells. There is an accumulation and retention of the diimino-phosphatide sphingomyelin within these cells.

Pathology.—The foamy Niemann Pick cells are not part of a granulomatous or inflammatory tissue as seen in the different types of xanthomatous disease discussed above. The liver, spleen and to a less extent, the lymph glands are enlarged. Histological examination reveals the presence of many foamy cells containing lipid in the bone marrow and elsewhere and may be demonstrated on marrow biopsy. The blood picture is normal. There is involvement of the central nervous system.

Course and Prognosis.—The disease begins in the first year of life with enlargement of liver, spleen, lymph nodes, anæmia, diffuse pigmentation of the skin and patchy bluish black spots on the mucous membranes of the mouth. Mongoloid facies is sometimes present. With physical and mental deterioration there is rapid progression to extensive cachexia and death occurs invariably within 2 years of birth.

Diagnosis.—Tay-Sachs disease (amaurotic family idiocy), in which there is lipoid degeneration of the central nervous system, may be confused with Niemann-Pick's disease. Cases have been described suffering from both conditions. The liver and spleen are not enlarged in Tay-Sachs disease. Gaucher's disease, see p 784, begins later in childhood and persists into adult life. Gargoylism is a lipoid disorder of the Tay-Sachs type in which skeletal defects, cranial deformity, mental deficiency and corneal opacification are associated with hepato-splenomegaly.

Treatment.—This is essentially symptomatic.

R. B. HUNTER.

SECTION XI

DISEASES OF THE LYMPHATIC SYSTEM

INTRODUCTION

THE lymphatic system consists of the lymphatic vessels (lymphatics), the thoracic duct, the lymph nodes or glands and many large and small collections of lymphoid cells scattered throughout almost every organ and tissue of the body. Examples of large collections are the tonsils, the Peyer's patches of the intestine, the Malpighian bodies of the spleen and the thymus gland.

Lymph flows from the tissues to the great vein at the base of the neck. It is carried in lymphatic vessels which begin in the tissues as naked endothelial tubes. How fluid gets into the lymphatic channels has been much debated. It has been suggested that they are actually pulled open when there is an increased amount of fluid in the tissues. Lymphatic vessels differ from capillaries in the possession of valves and supporting walls consisting of connective tissue cells. The flow of lymph depends on muscular contraction, respiration and gravity. The lymph enters the lymph glands by afferent lymphatic vessels and within the node the lymph spreads out under the capsule in a space called the peripheral sinus. From there it seeps into the substance of the node along sinuses lined with reticulo endothelial cells. All the internodal streams flow together at the hilum of the lymph gland to join the efferent lymphatic vessels. Thus the fluid from the tissues is presumably filtered in its passage through the lymph gland. There are many follicles in the node and it is claimed that the large pale cells at the centre of each follicle constitute the "germinal centre" in which new lymphocytes are formed. It is possible that they also have a reticulo endothelial function.

The thymus gland is also double in structure, the larger cortical part being chiefly composed of ordinary lymphoid tissue while the smaller medulla (Hassall's corpuscles) is epithelial in origin.

DISEASES OF THE THORACIC DUCT

Apart from obstruction of the duct by tumours, usually malignant, either within or pressing on the duct, and less often by tuberculosis, aneurysm and lymphadenoma, lesions in this situation are rare and are very difficult of recognition during life. Obstruction results in chylous pleural effusion and (or) chylous ascites. Since chylous ascites may occur without obstruction to the thoracic duct, as in tuberculous peritonitis, pleural effusion is better evidence of a thoracic duct lesion than is a milky ascites. But even here the diagnosis is by no means certain on this fact alone. Chyluria, with chylous oedema of the genitals and lower extremities, if occurring with one or both of the above does, however, make diagnosis of obstruction to the thoracic duct almost certain.

DISEASES OF THE LYMPHATIC VESSELS AND GLANDS

LYMPHANGITIS—Acute or chronic inflammation of the lymphatic channels is commonly found in infections, and in acute lymphangitis there are reddish lines in the skin. They often reveal the site of the infection and there is soon an associated enlargement and tenderness of the regional lymph nodes. Always an indication for

prompt treatment lymphangitis is particularly serious in limbs where the blood supply is impaired. Chronic lymphangitis is usually tuberculous in origin.

Treatment—Active treatment with antibiotics is urgently indicated.

ACUTE LOCAL LYMPHADENITIS is generally associated with acute lymphangitis and is due to the same causes—acute septic inflammation of the skin or mucous surfaces in the region drained by the affected lymphatics. The lymphatics associated with the fauces are those most often involved for obvious reasons. The tender and swollen nodes may suppurate, in which case the inflammation spreads leading to peri adenitis and involvement of the skin.

ACUTE GENERALISED LYMPHADENITIS—This occurs in almost all the acute infectious diseases but is particularly frequent and therefore of special diagnostic importance in German measles, measles, scarlet fever and diphtheria. In glandular fever there is generalised lymphadenitis associated with mononucleosis.

TUBERCULOUS LYMPHADENITIS—Lymphatic channels and glands are invariably involved in tuberculosis and in primary tuberculous infection it is the mediastinal and mesenteric glands which are affected. Involvement of the cervical glands is common particularly in children, in some cases the tonsils are tuberculous and therefore should be carefully examined. The cervical glands may be invaded on one or both sides of the neck. Pain is not a feature. The condition may regress with medical treatment but often the glands become matted together and caseation occurs. In order to prevent the formation of a chronic sinus the caseous material should be evacuated through a small incision. Widespread dissection of the glands should not be attempted but a period of treatment with streptomycin and other chemotherapeutic agents (p 1033) may be necessary. They are of value in promoting healing when caseous glands have been evacuated.

For the treatment of intra thoracic and abdominal tuberculosis see pp 720 1031

Local tuberculous enlargement of the lymph glands in the axillæ or groins or generalised enlargement, are so rare that other diseases should always be suspected.

LYMPHŒDEMA

Obstruction of lymphatic drainage by external pressure or low grade inflammation may lead to œdema of the extremities. In the tropics filariasis is a common cause see p 327. Obstruction is commonest in the lower limbs.

Lymphœdema is also found without evidence of inflammation or pressure and may be due to an abnormality of the lymphatic channels. It can occur at puberty and disappear later. Milroy's disease is the familial type. At first the œdema is on pressure but later the tissues compress with difficulty and elevation of the limb does not relieve the swelling. Though painless the deformity is distressing to the patient.

Treatment—It is unfortunate that the majority of cases of lymphœdema occur in the female sex because elastic stockings provide the simplest and best treatment in the early stages of the condition. Rest and frequent elevation of the limbs is also necessary. These measures should be employed early in order to postpone thickening of the tissues by fibrosis and later the liability to skin infections. When the condition is caused by filariasis the treatment is of that condition (p 328). It is essential to eradicate any infection in particular epidermophytosis.

NEOPLASTIC DISEASE

Lymphatic node enlargement may be due to carcinoma or sarcoma. In carcinoma the involvement is secondary and its situation and line of spread are often of critical importance in diagnosing the site of the primary growth. Primary lymphosarcoma

is dealt with separately (p. 791). Rhabdomyosarcoma occasionally produces secondary growths in lymph nodes.

Enlargement of lymphatic glands, local or general, in Hodgkin's disease and chronic lymphatic leukaemia, is discussed elsewhere.

HODGKIN'S DISEASE

Synonym.—Lymphadenoma.

Definition.—A disease principally affecting the lymph nodes which become enlarged, remain discrete and of rubbery consistence. The enlargement is not associated with pain. Commencing in one group of lymphatic glands it spreads to others and also to the lymphoid tissues of the spleen, liver and other organs. Rarely is there softening or necrosis of the enlarged lymph glands and the capsule remains intact.

Ætiology.—This is unknown. Most observers favour a neoplastic cause, though many of the features in the histological picture could be explained by an infective process.

It is important to recognise that the disease may occur at any age but its incidence is highest between the ages of 10 and 50. Seventy per cent. of the cases are males. There is no proof of hereditary tendency though occasionally cases are seen in two or more members of one family. It may coexist with tuberculosis and occasionally appears to follow an infective process of a pyogenic or spirochætal nature, though there is no proof at the moment that this is anything other than coincidental.

Pathology.—The disease process may involve isolated groups of lymph nodes in different regions of the body and when this happens the enlarged nodes tend to remain discrete, have a rubbery consistence on palpation and on section show yellow strands passing in from the intact capsule with whitish tissue between them. Areas of necrosis are unusual. Less commonly, at the onset of the illness the process may be widespread, involving in particular abdominal and intrathoracic lymph glands. Very rarely cases have been reported which would appear to be Hodgkin's disease where the spleen alone has been involved.

From post-mortem examinations it is clear that the retroperitoneal and para-aortic lymph nodes are the most frequent primary sites of the disease. This is an important finding and it contrasts sharply with the clinical observation that the cervical nodes are the primary site in a large percentage of cases. The difficulty of recognising involvement of the deeper nodes during life should make the physician very cautious in concluding that the disease is confined to comparatively localised superficial nodes. It is important in doing biopsy studies that a lymph node of the axilla or the neck should be used. Inguinal glands are frequently the site of secondary infection.

Microscopic examination reveals a great proliferation of the reticulo-endothelial cells, hyperplasia of the lymphoid cells and a mixture of plasma cells and eosinophil leucocytes. Certain endothelial cells which have been termed Reed-Sternberg cells are 12 to 40 microns in diameter, their shape is irregular and their cytoplasmic processes frequently extend to neighbouring cells. The nucleus in its most characteristic form is lobulated or multilobed and a nucleolar mass is present. The nature of these cells is obscure but it is their presence together with eosinophil cells which constitutes the most characteristic feature of the lymphadenomatous lesion. The spleen is involved in the disease process but great enlargement is unusual. The organ is firm, it preserves its natural contours, and the surface may be slightly irregular or finely nodular. The liver is frequently involved.

Apart from the generalised lymphadenoma, almost every organ of the body with the exception of the central nervous system proper may be affected.

Symptoms.—In a great majority of cases the first symptom is painless enlargement of the lymph nodes in the cervical region. They may be situated in the anterior or posterior triangles or under the sterno-mastoid. Occasionally enlarged glands are

first noted after an acute upper respiratory infection. This may lead to confusion and delay in diagnosis but persistent masses of glands in the neck after minor infections must be regarded with suspicion, particularly if the posterior triangle or the supra-clavicular region is involved. Full investigation is often delayed because the patient does not feel ill and at this stage there may be no clinical evidence of disease elsewhere. Pain, usually in the abdomen or back, or enlarged axillary lymph nodes are less common presenting features. Weeks or months may elapse before any other symptoms appear.

There is an acute type of the disease which may be associated with generalised superficial lymph node involvement or the deep lymph nodes may be principally and primarily involved. The clinical state may simulate an acute infection such as military tuberculosis. The most difficult cases to diagnose are those of primary involvement of the intra-abdominal lymph glands alone.

Course.—Two groups of symptoms develop in the more insidious case—the general symptoms of the disease and those referable to pressure and infiltration of the lymphadenomatous masses in *different organs* and tissues of the body. The most prominent symptom is generalised weakness and if the mediastinal glands are involved or the patient be anæmic, breathlessness on exertion may also be a feature. Loss of weight, pyrexia and pruritis which may be intractable, are common. This is the stage of the disease which is frequently seen on first admission to hospital, and the clinical condition may simulate tuberculosis. The pyrexia may have a characteristic undulant character, and its recognition is of great importance in diagnosis. It is a feature commonly missed, particularly in domiciliary practice. Sometimes the fever follows a regular pattern—waves of pyrexia of 4 to 14 days' duration alternating with periods of apyrexia. Such pyrexia is referred to as the "Pel-Ebstein" type. In rapidly progressing cases with widespread involvement a continuous type of pyrexia may be present, making it necessary to differentiate the condition from the enteric group of diseases.

Because of the widespread nature of the disease a multitude of local symptoms and signs may be present. For example, mediastinal pressure may cause a distressing dyspnoea and cyanosis, laryngeal palsy may be present and if bilateral may necessitate tracheotomy. Enlargement of the hilar glands and invasion of the peri-bronchial tissues may produce collapse of the lungs, pleural effusions or lung abscess. Masses in the liver may cause obstructive jaundice and ascites. In the later stages of the disease the bones may be extensively involved. Paraplegia has occurred as the result of involvement of the meninges.

THE PERIPHERAL BLOOD PICTURE.—Though there is a marked deviation from normal in cellular elements of the blood, there are no special features to help in establishing the diagnosis of lymphadenoma. A variable degree of hypochromic, or much more rarely normochromic anæmia develops in a large proportion of cases, particularly in the late stages of the disease. The pathogenesis of this anæmia is uncertain in some cases it is obviously due to involvement of the bone marrow but this is not invariably so; hypersplenism, see p. 781, may be the cause. In rare cases there is severe hæmolytic anæmia simulating acquired hæmolytic anæmia. In these cases there may be pseudomacrocytosis and increased fragility of the red cells. There is a wide variation in the white cell picture in the peripheral blood. Marked fluctuation in the white cell count may occur in a short period of time without apparent cause. Persistent leucocytosis is extremely frequent though a persistent leucopenia may occur. The most significant change in the differential white cell count is a relative or absolute increase in the percentage of neutrophil polymorphonuclear cells. In 10 to 15 per cent. of cases the absolute eosinophil count exceeds the upper limit of normal (400 per c.mm.). In spite of much that has been written on the importance of eosinophilia in the diagnosis of Hodgkin's disease, a very high eosinophil count suggests that it should be reconsidered. Monocytes are frequently increased in

number. A normal blood sedimentation rate is usually found in patients in a chronic phase of the disease and a rising rate usually indicates that the condition is rapidly spreading. An exception to this rule is found when the liver is massively involved.

Clinical Diagnosis.—Cases often present in one of three ways—patients with localised lymphadenopathy, those with generalised lymphadenopathy, and those with constitutional symptoms associated with little or no enlargement of the superficial nodes.

When confronted with localised lymphadenopathy, the condition has to be distinguished from other neoplastic conditions such as lymphoma, lymphosarcoma, reticulum-cell sarcoma as well as from tuberculosis, infective mononucleosis, syphilis and leukaemia. The two diseases which are confused with Hodgkin's disease most commonly are tuberculous adenitis and lymphosarcoma. Biopsy is the only sure means of establishing the diagnosis, and even then the tissue examined may not show the characteristic changes.

When generalised lymphadenopathy is present the condition most commonly confused with the disease is leukaemia.

The febrile type, in which no superficial lymph nodes are enlarged, presents great difficulty, and the diagnosis is arrived at principally by exclusion. Marrow biopsy is justifiable under these circumstances. The diagnosis is sometimes not made until necropsy.

Treatment.—There is no specific treatment for the disease but there are a number of therapeutic measures which will alleviate symptoms if not prolong life. Whenever possible a biopsy should be performed prior to therapy and a detailed clinical and radiological examination carried out.

Radiotherapy is the most valuable form of treatment available. Close collaboration between the clinician and the radiotherapist is essential for the best results. The form of treatment, local or wide field therapy and the dosage and frequency of treatment have to be decided in each case. Usually the first course of therapy lasts 2 to 3 weeks, treatment being given daily. The patient's general health has to be carefully watched during therapy. Frequent blood examinations should be carried out to detect any signs of bone marrow depression. "Nitrogen mustards" should be reserved for cases where further irradiation is contraindicated or for the acute form of the disease. Apart from these measures treatment is symptomatic.

LYMPHOSARCOMA

Definition.—Lymphosarcoma is a highly malignant tumour composed of mature or immature lymphocytes. Neighbouring structures are invaded at an early stage in the disease. Widespread metastases are uncommon except in those cases in which leukaemia develops.

Ætiology.—This is unknown.

Pathology.—The site of origin is usually in the cervical lymph glands, less commonly in the tonsil, mediastinal glands or the lymphoid tissue of the intestine. The tumour may vary greatly in appearance. Sometimes the outline of the lymph nodes is still recognisable, while in other tumours it is not. The colour of the tumour is white or pinkish and areas of necrosis are not infrequent. The section has a homogeneous appearance and histologically it is composed of mature lymphocytes or lymphoblasts. Neither giant cells nor multi-nucleated cells occur and the reticulum of the glands is not increased.

The greatest difficulty in differential diagnosis is to distinguish lymphosarcoma, especially of the lymphoblastic type, from reticulum cell sarcoma. In reticulum cell sarcoma, the cytoplasm of the cells is rather more abundant, the nuclei are usually slightly larger than those of an adult lymphocyte, and are irregular in shape. The reticulum is greatly increased, occurring in fine strands around groups of cells and

between individual cells. In the later stages of both diseases distant metastases occur in the lymph nodes, the spleen which is not often enlarged and throughout the body. Distant metastases are probably commoner in reticulosarcoma.

In children lymphatic leukaemia may be preceded by a local lesion with the characters of lymphosarcoma.

Symptoms—Initial symptoms of lymphosarcoma are rather strikingly different in the young and in the old. The disease is commonest in the first two decades and in the elderly. In childhood enlarged cervical lymph glands are frequently noted first. The children are often pale and petechiae may be present in the skin, and in fact these children are usually found to have an acute leukaemia. In adult cases the patients may remain well for quite a time and complain only of a mass in the neck, a sore throat or cough. The peripheral blood picture shows nothing characteristic. Fever is much less common in these adult cases.

Course—The disease progresses steadily to death. In children this occurs within a few months, though in the elderly the patient may live for 3 or 4 years.

Treatment—Great alleviation in symptoms and marked temporary improvement in general health may result from radiotherapy. Localised masses will disappear with the greatest rapidity but the cases in which the most satisfactory response occurs are often those in whom relapse is also rapid.

RETICULUM CELL SARCOMA

Synonym—Lymphosarcoma reticulum cell type

Many still regard reticulum cell sarcoma as a variety of lymphosarcoma. There are however many differences between the two types of neoplasm. As mentioned above a number of cases of lymphosarcoma are accompanied by lymphatic leukaemia. If leukaemia occurs in relation to reticulum cell sarcoma it is of monocytic type. Reticulum cell sarcoma of bone is also an important variety of primary bone tumour, whereas lymphosarcoma of bone is never primary. Whereas lymphosarcoma is common in early years of life, reticulum cell sarcoma occurs chiefly in the fifth, sixth and seventh decades. When it does occur under the age of 20 the disease is always a primary disease of bone.

Symptoms—The commonest initial symptom is pain which is often constant and is resistant to radiotherapy. It is most common in the neck or in the abdomen. Enlarged lymph nodes usually in the cervical region are frequent early in the course of the disease and they are occasionally painful. In sharp contrast to Hodgkin's disease these enlarged lymphatic glands are fixed to the underlying tissues and tend to be stony hard rather than of rubbery consistence. In reticulum cell sarcoma neither the mediastinum nor the lungs are involved nearly so commonly as in Hodgkin's disease or in lymphosarcoma. The liver and spleen do not enlarge to the same degree as in Hodgkin's disease. Involvement of the pharynx is common in reticulum cell sarcoma and rare in Hodgkin's disease.

Course and Prognosis—Loss of weight and pain are the commonest features of the course of the illness and both may be extreme. Pronounced fever on the other hand unless due to sepsis is rare and the so called Pel-Ebstein fever does not occur in this condition. The disease progresses at very different rates and in some cases surgical treatment and radiotherapy of the metastatic masses may prolong life for years. In others the end comes rapidly.

Diagnosis—The clinical diagnosis of reticulum cell sarcoma cannot be made with certainty and a biopsy is necessary. The disease may be indistinguishable from Hodgkin's disease on histological section.

Treatment—Radiotherapy offers the only hope of improvement. Response to therapy is not always so marked as in lymphosarcoma.

R. B. HUNTER.

SECTION XII

DISEASES OF THE CARDIO-VASCULAR SYSTEM

GENERAL CONSIDERATIONS

The function of the heart and blood vessels is to supply all tissues of the body with adequate oxygenated blood. The cardiac output is the effective volume expelled by each ventricle in a minute, and it varies between 4 and 6.5 litres per minute at rest with an average of 5.3 litres. The output with each beat averages between 70 and 80 ml when the heart rate is 72 per minute. An increase in heart rate or an increase in stroke volume causes an increase in cardiac output. Blood is ejected into the great vessels against peripheral resistance thus creating arterial pressure, and each separate ventricular systole causes a pulse pressure wave. The resistance offered in the systemic circulation is much higher than that in the pulmonary circulation, thus the arterial pressures differ in each circulation by a corresponding degree, although the output of the two ventricles is equal, the difference in the thickness of right and left ventricles reflects the difference in resistance against which each works.

The cardiac output varies greatly under physiological conditions, changes in venous return are largely responsible for significant changes in cardiac output, which are brought about by alterations in stroke volume and heart rate. Cardiac output decreases with a change to the upright position because of a fall in venous return, it increases with emotion and may increase fivefold or more on exercise in a trained athlete. The arterial pressure remains relatively constant because these physiological variations in cardiac output are balanced by reciprocal changes in the tone of the peripheral vascular system. The cardio-vascular system functions as a whole, changes in one variable factor are offset by alterations in others and there is integration of the whole system through the autonomic nervous system.

The heart beat is initiated at the sino auricular node, from which the auricles are activated by the stimulus which passes over them in a cephalo-caudal direction to the auriculo-ventricular node. The auricles function as low-pressure receiving reservoirs and they augment ventricular filling by contraction at the end of diastole. Systole of the right and left auricles is almost simultaneous, and the left functions at a slightly higher pressure than the right. The clinical manifestations of auricular contraction are an "a" wave in the jugular venous pulse, a soft auricular sound which forms the early vibrations of the first heart sound, and the "P" wave of the electrocardiogram.

The cardiac stimulus passes through the junctional tissues of the auriculo-ventricular node and is conducted to the ventricles by the right and left branches of the bundle of His, and the Purkinje network. The function of the ventricles is to eject blood into the high-pressure arterial systems. In systole the auriculo-ventricular valves are closed, and each ventricular chamber and its outflow tract to the aorta or pulmonary artery behaves as a smooth continuum, after the peak pressure is reached relaxation follows and the semilunar valves close, preventing the regurgitation of blood and thereby creating a diastolic arterial pressure. The clinical manifestations of ventricular systole are the arterial pulse wave, the "c" wave in the jugular venous pulse, the lift of the apex beat, the first heart sound and the QRS complex on the electrocardiogram. The second sound which occurs at the end of systole is normally split into two sounds from asynchronous closure of the semilunar valves. When the

intraventricular pressure has fallen low enough for the auriculo-ventricular valves to open, ventricular filling starts and it is completed by auricular systole. Impulse formation and its conduction over the heart is further described in the section on arrhythmia (see p 819).

The normal basal systemic arterial pressure is between 100 to 145 mm Hg in systole and between 60 to 90 mm Hg in diastole. Considerably higher figures may be recorded in normal subjects at a casual examination, but after rest and reassurance the blood pressure falls. The elasticity of the normal aorta damps the initial systolic thrust so that as the aorta loses elasticity with increasing age, systolic pressures tend to rise. The normal pulmonary artery blood pressure is between 15 and 25 mm. Hg in systole and between 6 and 10 mm Hg for the diastolic level. The pulmonary capillary pressure may be obtained by passing a cardiac catheter into a branch of the pulmonary artery to the point of blockage, and in this wedged position the pressure and pulse wave forms appear to be a direct reflection of the dynamics of the left auricle.

SYMPTOMS IN HEART DISEASE.—There are relatively few symptoms of cardiovascular disease but it is most important to obtain a detailed account of each, in most cases this necessitates a searching enquiry by direct questions, the results of which can only be interpreted with a knowledge of the patient's emotional state and level of intelligence. *Dyspnoea* on effort is the first and most sensitive indication of cardiac failure. It is due to diminished vital capacity, congestion of the pulmonary vascular bed and reflexes arising therein which abbreviate the depth of respiration and increase its rate. *Dyspnoea* may be due to primary lung disease or obesity, but a carefully taken history will often reveal a subtle but significant change when cardiac dyspnoea is superimposed on dyspnoea due to these other factors. Respiratory symptoms associated with psychoneurosis, such as sighing and tachypnoea, are readily distinguished from those due to organic disease. *Pain* in heart disease is mostly due to cardiac ischaemia, pericarditis or psychoneurosis. The type of pain, its site and radiation, provoking and relieving factors and natural history must be known before a diagnosis and full assessment can be made. *Palpitation* is an awareness of the heart beating due to an increase of rate, force or an arrhythmia. It is a frequent symptom of neurotic ill health, but is common in heart disease and thyrotoxicosis. *Fatigue* and weakness are often symptoms of neurosis, but may also be due to a low cardiac output from chronic valvular disease. *Syncope* is loss of consciousness due to acute systemic arterial hypotension. An adequate history usually distinguishes syncope from unconsciousness due to primary cerebral causes. Simple fainting is vasovagal syncope which, like other symptoms of cardiac disease, may be associated with psychoneurosis. *Giddiness* is the term used by patients to mean various sensations such as vertigo, a sensation of dimmed vision, a pressure on the head, general weakness or even local weakness in the legs. This symptom thus always requires careful analysis with particular reference to near syncopal reactions and true vertigo.

PHYSICAL EXAMINATION IN HEART DISEASE.—Examination should include a general inspection of the patient, a detailed examination of the cardio-vascular system and of any other systems indicated. Appearance and demeanour may reveal anxiety or depression, other signs such as dyspnoea, wheeziness, cyanosis, obesity, malnutrition, pallor, icterus and goitre may be observed whilst obtaining the history. The hands and skin should be inspected, structural abnormalities of the hands may be associated with congenital heart disease, coldness, pallor and blotchy cyanosis indicate peripheral vascular constriction, whilst hot, moist hands with pulsation of digital vessels may indicate anxiety or a state of high cardiac output. Hyperhidrosis is also a feature of the rheumatic state, when a diffuse swelling of digital joints and nodules may be found. Inspection of the nails may show such important signs as clubbing, undue pallor, capillary pulsation, koilonychia or splinter haemorrhages. Changes in texture of the skin are important pointers to disturbed water balance, endocrinopathy and

collagen diseases Skin rashes are obviously important and are often related to previous medication

EXAMINATION OF THE CARDIO VASCULAR SYSTEM—Arterial and venous pulses should be examined first, then the peripheral signs of heart failure should be sought and the examination is completed with inspection and palpation of the præcordium and auscultation of the heart. *The venous pulse* should be examined with the subject reclining at approximately 45° , in normal subjects it appears just above the clavicles in this position. The upper limit of a normal pulse wave is 3 cm above the sternal angle. Normally there are three positive waves: a sharp "a" wave due to auricular systole, a small "c" wave due to ventricular systole and largely transmitted from the adjacent carotid, and at the height of auricular filling a blunt "v" wave whose apex just precedes the opening of the auriculo-ventricular valves, signified by a steep trough in the venous pulse. The venous pressure may be generally elevated in heart failure, pericardial tamponade, constrictive pericarditis and mediastinal obstruction, or individual waves may be augmented, diminished or absent. The jugular venous pulse is distinguished from the carotid arterial pulse by the following features: (1) triple wave form, (2) the diffuse undulating nature of the pulse which is seen over a relatively large area, (3) an upper level of pulsation (which, however, may not be seen when the venous pressure is very high), (4) variation of the level of pressure with respiration and an increase in the distinctiveness of the separate waves with inspiration, (5) elevation of the level of the venous pulse in the neck by hepatic pressure, and (6) obstruction of the venous pulse by relatively gentle pressure at the root of the neck. The auricular "a" waves have a sharp, "flicking" form and are presystolic in time. They are augmented in conditions which cause auricular systolic hypertension and thus are largest in tricuspid stenosis and when auricular systole is obstructed by closed auriculo ventricular valves, as in the occasional coincidence of auricular and ventricular systole in heart block, "a" waves are also augmented in conditions of right ventricular hypertension such as pulmonary stenosis and pulmonary hypertension. Large fused "cv" waves coinciding with ventricular systole, having a large pulse volume, appearing to rise rather slowly and followed by a diastolic collapse, are characteristic of tricuspid incompetence and may be confused with a Corrigan pulse in the carotid arteries.

The arterial pulse is traditionally examined at the wrist, but both radial pulses and the brachial vessels should be palpated and where there is any difference in these pulses, or if hypertension is present, the subclavian, carotid and femoral pulses should also be felt. The pulse pressure and volume determine the size of the pulse, the level of the blood pressure is difficult to determine without a sphygmomanometer, although a rough estimate may be made by compressing the brachial artery with the thumb whilst the fingers of the right hand are used to detect the point of obliteration. Pulse volume is increased when the stroke output is increased in high cardiac output states, in aortic incompetence, and, to a lesser degree, in mitral incompetence. The pulse appears full and bounding and often pulsation can be felt as far as the digital arteries, the hands are warm and often moist. The pulse is diminished in low cardiac output states and when there are obstructive lesions such as aortic stenosis and mitral stenosis. Aortic valve disease causes a change in the pulse wave form apart from an alteration in its volume, aortic stenosis causes a notched and flattened wave—the anacrotic pulse, whilst aortic incompetence (and other causes of a rapid leak from the arterial system such as patent ductus arteriosus or arterio venous aneurysm) causes a water hammer pulse. Combined aortic stenosis and aortic incompetence produces a deeply notched pulse—the pulsus bisferiens. An absent peripheral pulse may be due to very low pulse pressures from an arterial obstruction (e.g. peripheral embolism or coarctation of the aorta), but the diastolic pressure and the resting blood flow to the area concerned may be within normal limits. The state of vessel walls is assessed by digital examination, the brachial vessels are always

thickened in established hypertension and further evidence of the state of the smaller vessels may be obtained by ophthalmic examination

Heart size and shape are most accurately determined by radiological methods. Percussion of the chest and palpation of the apex may be illusory, however the position of the apex beat is a reliable guide to heart size when its displacement is not due to deformity of the thorax, fibrosis of lung or pleural effusion and when apparent displacement is not due to great overactivity as in thyrotoxicosis. Percussion of the præcordium reveals relatively gross changes in size to right or left, and is helpful when the apex cannot be felt when emphysema is present, but many physicians now regard evidence from percussion of the heart with suspicion.

Abnormal pulsations of the heart may be detected by observation and palpation and are of great significance in diagnosis. The hyperdynamic heart of anxiety thyrotoxicosis and other high output states causes an increased pulsation of the whole præcordium and apex. In conditions with a left to right shunt such as auricular septal defect the increased activity may become very great, affecting the whole præcordium or it may be more or less confined to the intercostal spaces over the right ventricle and pulmonary artery. Equally significant but much more difficult to appreciate is the quiet heart of a pericardial effusion, myxœdema or a primary cardiac pathy. In left ventricular hypertrophy the apex beat is strong and appears to be sustained but when ventricular dilatation develops the beat eventually loses its heaving quality. Right ventricular hypertrophy is characterised by a systolic heave or lift in the parasternal region and præcordium; this is felt by placing fingers in the intercostal spaces or placing the flat hand along the parasternal region over the right ventricle and pulmonary artery; sometimes it is best appreciated by placing the fingers high in the epigastrium and directed towards the right ventricle. In right ventricular hypertrophy the apex beat is rather localised and is still formed by the left ventricle which appears to tilt forward on the enlarged right ventricle. Pulsation of the right ventricle merges into that of the pulmonary artery at the level of the third interspace. The vibrations caused by heart sounds and murmurs can be palpated when of sufficient intensity and they are often superimposed on the pulsations described above. The tapping quality of the apex in mitral stenosis is due to left ventricular systole together with an appreciation of the loud and sharp first heart sound. In pulmonary hypertension the diastolic shock of valve closure may be felt as well as the systolic thrust of the tense pulmonary artery.

Heart sounds and murmurs are vibrations set up by the main events in the cardiac cycle and are essentially recognised by auscultation but when of sufficient intensity they may be appreciated by palpation. Heart sounds and murmurs may be recorded by phonocardiography (see below). *Technique of auscultation*. The stethoscope should have well fitting earpieces and moderately thick tubing between 10 and 15 in. long—chest pieces are of two types, bell and diaphragm and available in a combined form; the bell end is better for low pitched sounds and murmurs, the diaphragm for high pitched ones. On auscultation it is essential to listen to one sound or murmur at a time and with practice the other sounds and murmurs may be actively excluded. The ear is more sensitive to higher frequencies than to the lower ones—low frequency vibrations must be of much greater intensity to bring them within the range of audibility. *Heart sounds*. The timing, pitch, intensity and site of maximal intensity should be noted for all sounds. The first heart sound is due to ventricular systole and the closure of auriculo ventricular valves. It is best heard in the mitral area and is preceded by a soft sound due to auricular systole. It often appears to be split and is soft when the P-R interval is long and it is loud and short when the P-R interval is short, and when there is tachycardia it also becomes very loud in mitral stenosis. Systole is normally silent and terminated by the second heart sounds which are due to the closure of the semilunar valves. Although usually referred to as the second heart sound there are essentially two components, aortic and pulmonary which are

slightly asynchronous. The second heart sounds are best heard in the second left intercostal space, where slight splitting, increased by inspiration, is physiological. The aortic second sound is the first component, and, being louder, is widely heard, and is the second heart sound at the mitral area. The later component is pulmonary and is softer. It follows that augmentation of either component reflects a rise of pressure in the vessel concerned, conversely when the pressures are low, valve closure is delayed and less violent, *z.e.* in pulmonary stenosis P2 is significantly late and soft. Asynchronous contraction of the ventricles due to bundle branch block leads to wide separation of the second heart sounds which is proportional to the degree of delay of systole in the affected ventricle. The third heart sound is the most important additional heart sound. It is associated with ventricular filling and occurs in early diastole. It is a low-pitched, soft thud, best heard at the mitral area (except in the case of right ventricular failure) and with light pressure of the bell-ended stethoscope. It is physiological in the young, its incidence diminishes up to the age of 40, and thereafter it is pathological, it occurs in all forms of heart failure, and when the heart rate is normal or slow it produces a protodiastolic gallop rhythm (triple rhythm). The third sound may become the loudest of the heart sounds in heart failure and when the heart rate is increased there is summation of the third heart sound and the next auricular sound, producing a presystolic gallop rhythm. In constrictive pericarditis the third heart sound is shortened and sharpened and occurs rather earlier in diastole than is usual, this may be due to the very high venous pressure and restriction of ventricular filling by the pericardium. In mitral stenosis rapid ventricular filling is prevented by the mitral obstruction so that a third sound is not heard, however, in pure mitral incompetence there is a free and augmented flow to the ventricle so that a third heart sound is usual. An additional sound, the opening snap, is heard in mitral stenosis. It is due to the diastolic opening movement of thickened inelastic mitral valves, but it disappears when such valves are completely rigid and calcified. It is short and sharp and best heard above and inside the apex. Added sounds in systole are not uncommon, their significance is not well understood but it appears that most are innocent. It has recently been shown, however, that a short sharp sound in early systole is associated with ejection when the great vessels are dilated beyond the semilunar valves.

Murmurs are due to a more prolonged series of vibrations than sounds. The timing, duration, pitch, intensity, variations with posture and respiration, site of maximal intensity and radiation should be observed in all murmurs. *Systolic murmurs*. It is customary to classify systolic murmurs in the first instance as either innocent or organic. The distinction has been largely based on loudness, but it is doubtful whether this is justifiable, since most loud organic systolic murmurs presumably start as soft ones, duration and quality are probably more important. Many systolic murmurs are related to deformities of the chest or very minor abnormalities in the heart, and as such they are of entirely benign significance but not necessarily innocent in the sense that there is no structural or haemodynamic cause for their existence.

Many children have a soft, mid systolic, parasternal murmur, especially when there is tachycardia—this is of no significance and may disappear in adult life. Soft, mid systolic murmurs in the parasternal region and over the pulmonary artery arc not uncommon in adults, some are due to an increased blood flow into the great vessels, *e.g.* in pregnancy, thyrotoxicosis and auricular septal defect, and others are associated with sternal depression or kyphoscoliosis. A soft, mid systolic murmur may occur in the parasternal region without evidence of an hyperdynamic circulation or heart disease, and these often diminish greatly with a change from a reclining to an upright posture and are regarded as innocent. The systolic murmurs of aortic stenosis, aortic sclerosis and pulmonary stenosis are also of maximal intensity in mid-systole—those arising in the aortic valve are best heard in the second right intercostal space and radiate to the neck and downwards towards the apex, those

arising in the pulmonary outflow tract are best heard in the third left intercostal space and radiate upwards to the left, and downwards. The systolic murmurs due to regurgitation from the ventricles, *i.e.* mitral and tricuspid incompetence and ventricular septal defect, tend to be heard throughout systole (pan systolic). In the case of mitral incompetence the murmur may be so loud and long at the apex that the second heart sound cannot be distinguished there, and it tends to radiate towards the left axilla. In tricuspid incompetence the murmur is not usually as loud as in mitral incompetence, it is heard best at the lower end of the sternum and varies with respiration.

Diastolic murmurs—All indicate heart disease. Incompetence of the aortic or pulmonary valves is shown by an early diastolic murmur which is high pitched and diminuendo, starting immediately after the second heart sound and often loudest in the third or fourth left intercostal spaces. These murmurs are best heard when the patient is in an upright position with the breath held in expiration. A diaphragm chest piece is superior to the bell for the detection of soft, early diastolic murmurs. The murmur of mitral stenosis is of much lower pitch and its onset is delayed well after the second sound, it is heard best at the apex and aptly described as a rumble. The presystolic murmur, or more accurately the auricular systolic murmur, follows the mid diastolic murmur of mitral stenosis, it is short and brisk, and its crescendo rises to the first heart sound. Mid diastolic murmurs also occur in conditions associated with an increased flow through the auriculo ventricular valves, *e.g.* auricular septal defect, ventricular septal defect and patent ductus arteriosus. Mid diastolic murmurs are best heard where the patient is reclining and half turned over to the left side, and by using light pressure over the apex with a bell end piece to the stethoscope. Continuous murmurs occur when the pressure on one side of a vascular fistula is higher than that on the other throughout the cardiac cycle. A continuous rushing noise is produced usually loudest in systole. Murmurs are often described in such terms as "blowing", "musical", "harsh", "machinery", "seagull", etc. There is little place for such inaccurate and unsatisfactory adjectives if murmurs are described in terms of loudness, pitch, duration and site of maximum intensity. **Phonocardiography** is a graphic method of registration of heart sounds and murmurs. By means of sensitive microphones, valve amplifiers and multiple galvanometers, synchronous records from various sites on the præcordium may be made and the characteristics of human hearing with the stethoscope may be represented. By this means permanent records of auscultatory findings at particular times in the natural history of the disease may be made. Heart sounds may be accurately timed and identified and the special features of various murmurs may be determined. At present the methods do not lend themselves to routine use for considerable technical skill and care is required, and quiet undisturbed conditions are necessary in order to obtain useful records.

Electrocardiography—When heart muscle contracts the polarised state which exists between the cell membrane and its cytoplasm is disturbed and total depolarisation follows, recovery is associated with repolarisation. These phases of ionic reorientation are accompanied by minute potential changes which are conducted in the surrounding medium. At maximal activity and at complete rest there is no change and no current flows. The heart is thus the source of electrical charges which are conducted through the surrounding medium in all directions to the body surface, and an electrocardiogram is the graphic registration of the surface potential changes by means of a galvanometer. Since the heart is completely surrounded by a varying electrical field it follows that the potential changes may be registered at any point on the body surface and at such points (or lead positions) the electrical changes represent the resultant electrical forces in the axis of the electrode.

In practice the electrocardiographic lead connections between the body and the galvanometer are of two types. (1) *Bipolar* when two electrodes are placed on different

points of the surface and the resultant potential differences existing between them are recorded. The standard leads of Einthoven are bipolar and obtained by connecting the left arm and right arm to form lead I, the right arm and left leg to form lead II, and the left leg and left arm for lead III. The apices of the hypothetical Einthoven triangle are formed by connections from the left arm, right arm and left leg, and the heart is considered to be lying in the centre and equidistant from each apex of the triangle. Bipolar chest leads are formed by connecting an exploring chest electrode and the right arm (CR leads). (2) *Unipolar* leads are formed by recording between an exploring electrode and an indifferent electrode which is formed by joining together three limb leads, each through 5,000 ohm resistances (Wilson). The exploring electrode may be used to record and measure the voltages from any point on the surface (V leads).

The horizontal components of the heart's electrical field are explored anteriorly by means of chest electrodes (either V or CR) at the following stations, which are conventionally designated 1 to 7 (CV or CR). 1 and 2 are at the level of the fourth intercostal space on the right and left sides of the sternum, 4 is at the level of the fifth left intercostal space in the mid clavicular line, and 3 is half-way between 2 and 4. Numbers 5, 6 and 7 are also in the fifth left intercostal space in the anterior, mid and posterior axillary lines. CR leads show slightly greater voltages than V chest leads and when recording from the routine stations C_1 to C_7 the differences are insignificant. The components of the central electrical field in the frontal plane are recorded in Einthoven's standard leads and by means of the unipolar limb leads VR, VL and VF, referring to the right arm, left arm and left foot connections of the exploring electrode.

The *normal electrocardiogram* consists of a series of waves arising from an isoelectric baseline and associated with each heart beat. By convention positivity is recorded above and negativity below the baseline. The P wave is caused by activation of the auricles and is the first wave. It is upright in standard leads and in left sided chest leads, but it is negative in VR and often inverted in V_1 . The duration of the P wave is usually 0.10 second or less and its amplitude varies from 0 to 2.5 mm. P waves are followed by a small recovery wave (auricular T wave), but this is not usually recognisable in the ensuing isoelectric part of the PR interval. The PR interval represents the time taken by an impulse from the sinus node to reach the ventricles, it is measured from the beginning of the P wave to the beginning of the ventricular complex and varies normally from 0.12 second to 0.21 second.

The QRS complex is the second and major series of deflections of the electrocardiogram and is due to ventricular activation. Q refers to any initially negative wave. R waves are positive waves and S waves are negative waves following positive deflections. Left ventricular activity dominates the electrical field during the phase of ventricular activation and its resultant positive axis is directed downwards and to the left, the surface components of this field are thus positive over a wide area of the left chest and leads taken from this area are said to show left ventricular complexes. It is probable, however, that such deflections are the resultant effect of the electrical activity from the whole heart. Dominant "left ventricular" complexes (qR pattern) may be obtained in any one of the standard leads, but mostly in lead I, and in left chest leads V_5 , V_6 and V_7 . Normally there is a small initial Q wave in leads I, II, V_6 and V_7 , it does not exceed 0.04 seconds in duration and is usually less than 2 mm. R waves in "good" left ventricular leads exceed 5 mm and are usually more than 10 mm high. The height of the R wave in the left chest leads added to the depth of the S wave in right chest leads should not exceed 35 mm. A short, brief S wave follows the R wave in leads I and V_7 and this wave deepens and widens as right sided lead stations are approached. In right-sided chest leads V_1 to V_3 , the ventricular complex is usually of an RS form, the height of R wave being from 1 to 5 mm and the depth of the S wave from 5 to 15 mm in V_1 . The R waves gradually increase across the chest to V_6 or V_7 and the S waves progressively

diminish. The total duration of the QRS complex is usually 0.08 second and should not exceed 0.10 second.

The direction of the greatest electrical potential in the frontal plane may be assessed from the direction of the main deflections in the standard leads. When the QRS is mainly positive in lead I, and mainly negative in lead III there is left axis deviation, which indicates a rather horizontal position of the electrical axis; this is found in thickset subjects with a high diaphragm, and often in patients with left ventricular hypertrophy. When the main QRS deflection in lead I is negative and in lead III is largely positive there is right axis deviation, which is associated with the vertical heart of tall thin subjects, with emphysema and with right ventricular hypertrophy.

The QRS complex is followed by the S-T interval and T waves. The S-T interval represents total activity of the myocardium and should thus be isoelectric; usually there is a slight upward curving slope from the end of the S wave to the T wave, but general deviation of the S-T segment from the baseline of 1 mm or more is pathological, and smaller deviations than this may be significant when taken in conjunction with the clinical and other electrocardiographic findings. The T wave is associated with recovery of the myocardium. It is normally upright in all standard leads but it may be inverted in lead III when the heart is horizontal, as in patients with obesity, and a high diaphragm, on deep inspiration, which moves the heart to a more vertical position, such negative T waves tend to become upright. The T wave is also often negative in lead V_1 , and in children the negativity of T waves from the right chest may extend to the left as far as V_4 . T waves are normally positive when the ventricular complex shows a left ventricular qR pattern. The Q-T interval indicates the total duration of ventricular excitation and recovery, it is normally an inverse function of heart rate and varies from 0.39 to 0.41 seconds at 70 beats per minute. The Q-T interval is prolonged by carditis and hypocalcaemia and shortened by digitalis. The U wave is a small deflection which follows the T wave and is positive in left ventricular leads, where it is best seen.

The abnormal electrocardiogram shows abnormalities of two different kinds. Firstly, disorders of the sequence of auricular and ventricular contraction and the time relations between successive cycles may be shown—these are the arrhythmias—and here the electrocardiogram confirms accurately abnormalities which may be detected by clinical examination. The electrocardiogram in the cardiac arrhythmias is described in the section on this subject. Secondly, a different type of information concerning the qualitative changes of individual QRS and T waves may be shown, such changes are due to alterations in the relative order in which different areas of myocardium pass through stages of excitation and recovery, and the abnormalities referred to in this group are associated with various clinical conditions but they have no direct clinical counterpart, e.g. there is no physical sign corresponding to a negative T wave. *Abnormalities of the P wave* P waves become tall (up to 5 mm) and sharp in right auricular hypertrophy, and are best seen in leads II and III, and in V_1 to V_3 , e.g. in congenital heart disease and pulmonary heart disease. Pathological P waves due to left auricular hypertrophy are seen in mitral stenosis, they are notched and widened and the two peaks correspond to right and left auricular activity respectively. When activation of the auricle starts at its caudal end the direction of activation is reversed, and P waves become inverted in lead III, VF and left chest leads, e.g. in nodal rhythm.

Abnormalities of the QRS-T complex—Left ventricular hypertrophy The first electrocardiographic sign of left ventricular hypertrophy is an increased height of left ventricular R waves. At a further stage the duration of the QRS is slightly prolonged and the T waves in left ventricular leads become flattened; in more extreme degrees the ST segment is depressed below the isoelectric line and it merges into an inverted T wave. Ultimately when ventricular muscle is greatly damaged, the voltage becomes lower, the duration longer and a left bundle branch block pattern with in

verted T waves may emerge. The changes of left ventricular preponderance are best seen in lead I, VL and left-sided chest leads. The tall R waves in I and deep S waves in III are due to left axis deviation which is mostly present, but occasionally the electrical axis may be more vertical (especially in aortic stenosis) and then the QRS-T changes of left ventricular preponderance are best seen in leads II, III and VF. *Right ventricular hypertrophy.* The normal preponderance of the left ventricle masks early right ventricular preponderance which is often difficult to detect without additional leads taken from the right side of the chest. The R waves of right pectoral leads are of increased amplitude and S waves tend to diminish. The R wave from hypertrophy of the right ventricle tends to occur slightly after the normal initial R wave in V_1 , so that a positive secondary R wave, producing a notched complex, appears in V_1 to V_3 and resembles the pattern of right bundle branch block. Right ventricular hypertrophy is reflected in V_6 to V_7 by a deepening of normal S waves and the standard leads generally show right axis deviation. In extreme degrees of right ventricular preponderance the R wave is not followed by an S wave in V_1 to V_3 and it exceeds the R wave in V_6 to V_7 and is followed by inversion of the T waves from V_1 to V_3 or V_4 .

Bundle branch block (intraventricular block) (see also p. 833). The essential feature of the electrocardiogram of bundle branch block is an increased duration of the QRS time; it is due to lesions of the intraventricular septum and also occurs as a transitory functional phenomenon in acute dilatation of the heart, e.g. in pulmonary embolism. Left bundle branch block is always associated with heart disease, whereas right bundle branch block may be innocent. *In left bundle branch block* the ventricular septum is stimulated from the right side, and activation of the left ventricle is delayed so that the normal initial Q wave of left ventricular leads (V_5 to V_6) is replaced by a small R wave from the septum, which is followed by a delayed R wave due to activation of the left ventricular muscle. This is reflected in late wide S waves after an initial R wave in right chest leads. The S-T segment is usually depressed below the iso-electric line and the T wave is secondarily inverted in leads showing the left-sided pattern. *In right bundle branch block* the initial deflections of the QRS are normal since the septum is normally stimulated from the left side. Leads V_1 to V_3 show that the small initial R wave is followed by a second and taller R wave from the right ventricle. V_5 to V_6 show the normal qR pattern followed by a wide S wave which reflects delayed right ventricular activation.

Myocardial injury.—Damage to the myocardium is shown in changes of the ventricular complex of the electrocardiogram. The cause is mostly ischaemia with or without infarction, but inflammation, infiltration, intoxication and trauma may occasionally produce similar changes. The degree and extent of damage may be assessed approximately from abnormalities of the T wave, S-T and QRS deflections and from the leads in which these changes are seen to occur. *The T wave* may become flattened and inverted in left ventricular leads from ischaemia and other injurious processes. The change is non-specific and reversible. In coronary disease the T wave inversions tend to be sharp and form a symmetrical triangle below the iso-electric line. Inversion may be transient and produced only by effort in the first instance, or a spontaneous transient inversion may be the only evidence of a small restricted infarction. *The S-T segment.* Deviation of the S-T interval may represent more severe degrees of injury and, though reversible, recovery may be slower than in the case of a fleeting T wave inversion. Injury to the endocardial layers of muscle causes S-T depression in surface leads "facing" the lesion, whilst relatively superficial injury causes an S-T elevation; the former change is seen in severe attacks of angina pectoris and in coronary insufficiency and S-T elevation is seen in pericarditis and in recent cardiac infarction. Leads recording from the opposite surface of the body to that which is adjacent to the underlying lesion show reciprocal changes in the S-T deviation, though these are usually of slighter degree, e.g. in posterior

cardiac infarction ST elevation is seen in lead III and VF, but precordial leads frequently show S-T depression. *The QRS deflection* Potential changes are not produced by necrotic muscle so that an area of cardiac infarction does not contribute to the R wave and in leads "facing" an area of infarction large negative waves (pathological Q waves) appear and are the result of positive potentials arising in remaining normal muscle and directed away from the exploring electrode. Pathological Q waves are of more than 0.04 second duration and usually more than 2 mm deep, they may occupy the whole QRS time (QS waves) or be followed by an R wave. The Q wave is a permanent abnormality but with time it may become smaller and the number of leads which show it may become fewer. Since few conditions other than infarction are responsible for local muscle death and replacement, it follows that the pathological Q wave is almost specific for this condition.

In acute cardiac infarction S-T elevation is often the first abnormality, it soon regresses but may persist. Q waves may appear within minutes or several hours after the onset of pain, but the T wave inversion often only becomes apparent as the S-T segment subsides towards the iso electric level. This pattern of cardiac infarction is always essentially the same, but these changes may occur in any lead, depending on the site of the lesion in the heart and the position of the heart in the thorax.

The common sites of infarction may be recognised by the following patterns:

- 1 *Anterior cardiac infarction*—Characteristic Q waves and T wave inversion are present in leads V_3 to V_6 with more or less distinctive changes in leads I, VL, V_3 and V_6 .
- 2 *Posterior cardiac infarction*—The deep Q waves and T inversion are found in leads II, III and VF. Physiological Q waves in lead III are not accompanied by changes in other leads and on deep breathing normal Q waves are diminished.
- 3 *Lateral infarction*—The changes of infarction are found in leads I, VL and V_7 and may be combined with anterior or posterior patterns.
- 4 *Septal infarction*—Q waves are present in V_1 , 2 and 3 (i.e. QS waves in these leads) and may be combined with either anterior or posterior patterns of infarction.

RADIOLOGY IN HEART DISEASE—Three important methods are used in radiological diagnosis of heart disease, radioscopy (X-ray screening) teloradiography (films taken at a tube distance of 6 ft. or more) and angiocardiology. Less frequently used methods are electro kymography and roentgen kymography, by means of which pulsations may be recorded, and tomography, which is a method of investigating structures at various depths in the thorax.

The radiological silhouette of the mediastinum shows the following structures from above downwards: on the right border a soft straight line, the superior vena cava, joins the sterno-clavicular joint to a gentle convexity due to the ascending aorta, at the lower end of which the hilar vessels protrude into the right lung shadow, below this a larger convexity due to the right auricle extends to the diaphragm below, where a soft straight line often interrupts the sharp angle between the auricle and diaphragm and is due to the inferior vena cava. On the left border the aortic arch forms a smooth, semicircular knob (diameter from 2 to 4 cm.) just below the sterno-clavicular joint, this meets a second and somewhat longer convexity—the pulmonary artery due to the main left branch of the pulmonary artery. Below this the short, flattened segment of the left auricular appendage joins the bold sweep of the left ventricle which meets the shadow of the diaphragm at a variable angle. On radioscopy all of these structures are moving. In systole the left ventricle moves sharply inwards and so does the right border formed by the right auricle whilst the pulmonary artery and aorta above move outwards. Pulmonary vessels form the hilar shadows and on

screening slight pulsation is normally seen in the main branches. Films taken at a fast exposure time are necessary to study the smaller lung vessels in detail—a fine arborisation of vessels may be seen almost as far as the pleura.

The oblique views provide further useful information. After screening in the antero-posterior position, the patient is rotated to the left so that the right chest is applied to the screen (the first or right oblique), the right arm is moved backward and the left forward; these adjustments are made by the operator and, with experience, a satisfactory view is soon obtained. In this view the anterior border of the mediastinal shadow comprises the aorta (the circumference of the arch may be seen) and a gentle curve due to the pulmonary artery, the upper part of the right ventricle, and the border of the left ventricle below. The posterior border may be outlined by a barium swallow and comprises: aorta, a lighter region due to the left main bronchus, and below this a slight gentle curve due to the left auricle, and a variable small part of the right auricle followed by a short, straight line due to the inferior vena cava. The second oblique or left oblique position is obtained by rotating the patient so that the left shoulder and chest are pressed to the screen; the arms are moved again to give a clear view. The anterior border is formed of two bold convexities, that above being due to the ascending aorta and that below due to the right auricular appendage and the right ventricle. The ascending aorta may be followed in a continuous backward curve over the arch to the descending aorta behind. Below the arch of the aorta a second arch, due to the pulmonary artery and its left main branch, extends from the base of the heart shadow to intersect the shadow of the descending aorta. Below this there is a large backward convexity due to left auricle above and left ventricle below—the latter extends backwards to reach the line of the descending aorta, and when the patient takes a deep breath the ventricle is separated from the anterior line of the dorsal spine by a short space. The point of intersection of the ventricle with diaphragm below is near the interventricular sulcus. In the frontal view the aortic valve lies almost in the centre of the heart shadow and slightly to the left of the mid line, whilst the mitral valve lies somewhat lower and slightly farther to the left. During radioscopic examination it is most important to view the whole chest, noting any deformity of the thoracic cage which may influence an assessment of heart size through displacement of the heart within the thorax.

The apparent size and shape of the heart vary greatly in normal individuals. Deformities of the thorax such as funnel depression of the sternum and kyphoscoliosis often produce gross deviations (usually to the left) which may be mistaken for enlargement. Radioscopy in all views, however, usually indicates the nature of the condition. Minor degrees of apparent enlargement may be found when there is bradycardia, in obese subjects when the diaphragm is high and the heart tends to be horizontal, and when there is epicardial fat seen as a soft triangular shaped shadow beyond the true apex. Very small hearts are seen in long lean individuals and as a result of wasting disease.

RADIOLOGY OF THE ABNORMAL HEART.—Investigation of cardio-vascular disease by radiology is largely concerned with the assessment of enlargement of the whole heart or its separate chambers and with changes in the vascular shadows of the lungs. **Pulmonary vessels.** Gross changes in the level of blood flow to the lungs are recognisable by radiology. Small, quiet branches of the pulmonary artery and generally right lung fields indicate a diminished blood flow (i.e. oligæmia); large, pulsating branches and a generally increased opacity of the lungs due to increased vascular markings indicate an increased blood flow (i.e. plethora or pleonæmia). Congestion of the lungs from heart failure is more common than plethora, the hilar regions are dense, the separate vessels become indistinct due to interstitial œdema, and the general increase of density extends for a varying distance into the lung fields and the vessels do not pulsate vigorously as in pulmonary plethora. Prominent interlobar fissures and effusions of varying sizes are also found in association with congestion.

The pulmonary artery—Enlargement of the main pulmonary artery shows as a bulge on the left border in the anterior view and as a large oval opacity below the aortic arch in the left oblique view. An enlarged main pulmonary artery may be associated with either plethora or oligæmia of the lung fields. In the young, in subjects with a vertical narrow heart, and in deformities of the thoracic cage with rotation of the heart, a normal pulmonary artery may appear enlarged.

The aorta—Dilatation of the aorta due to syphilitic aortitis may be diffuse, or local and aneurysmal (see also p 853). In the anterior view, enlargements of the aorta cause a widening of the superior mediastinum from bulging of the ascending aorta on the right or dilatation of the arch and descending aorta on the left side. A similar widening or localised bulging of the mediastinal shadow may be produced by unfolding of the aorta in hypertension, tortuosity of the aorta from degenerative changes and by mediastinal tumours. Calcification in the wall of the aorta is often helpful in the diagnosis of these conditions. A barium swallow outlines the posterior border of the arch and is an aid to assessment of its diameter. Irregularities of the descending aorta may also be outlined by deviation of the barium-filled œsophagus. Localised pulsation, though not expansile, is sometimes transmitted to tumours; on the other hand, an aortic aneurysm when filled with clot may show no pulsation. Excessive pulsation of the whole aorta is usually due to aortic incompetence, but may be due to a high cardiac output. When due regard is paid to the appearance in all views, it is usually possible to distinguish syphilitic dilatation from other conditions, but when doubt remains, angiocardiology can show clearly the course of the aorta and the calibre of its lumen. Coarctation of the aorta may be recognised by the absence of a normal aortic knuckle, rib notching and enlargement of the ventricle. Here also angiocardiology is necessary if accurate anatomical details are required.

The auricles—The enlarged right auricle bulges from the lower half of the cardiac shadow into the right lung field and meets the diaphragm at a variable angle. The right auricle is often greatly enlarged in congestive heart failure, especially when there is tricuspid incompetence, it is usually associated with enlargement of other chambers but it is selectively enlarged in organic tricuspid valve disease. An enlarged left auricle also bulges on the right border, but at a higher level than the right auricle, and when both are enlarged the right border of the heart below the aorta is formed by two graceful, intersecting arcs. The left auricle is also seen as a characteristic hump below the pulmonary arc on the left border of the heart, and sometimes the whole contour of this chamber may be seen through the heart shadow. Its size and minor degrees of enlargement are best assessed in the right oblique view, with a barium swallow. As the barium is followed down, it changes its course by turning backwards just below the level of the bronchus at the upper end of the left auricle, it continues in a gentle curve almost to the lower margin of the heart shadow—the patient should be turned to and fro in this oblique position until the maximum backward displacement of the barium is best seen. A small left auricular curve is often seen in normal subjects, but this can be straightened with a deep inspiration. In some patients, when the barium-filled œsophagus appears as a straight line in the right oblique view, a large left auricle can be best seen in the left oblique view. Expansile pulsation of the left auricle in ventricular systole is seen in severe degrees of mitral incompetence. In the anterior view both right and left borders of the auricle are seen to protrude beyond the cardiac shadow when the ventricle moves inwards in systole.

The ventricles—The right ventricle does not form a distinctive border of the heart in any view on radioscopy so that its enlargement is not easily recognised. With considerable right ventricular enlargement the heart may appear relatively normal sized in the anterior view, but the apex is often high and the left border rather straight above and below it. In the left oblique view the angle between the aorta and the anterior border of the right heart is sharpened, producing a more

globular heart shadow. The left ventricle enlarges backwards as well as outwards. In the anterior view the ventricular part of the left border develops a bold curve, and extends farther to the left, in the second oblique view the left ventricle extends backwards, often well into the vertebral shadow. An acute angulation or local bulging on the left ventricular border indicates a ventricular aneurysm and on screening the swelling may bulge outwards as the apex is withdrawn in systole.

ANGIOCARDIOGRAPHY—Radiography of the heart chambers and great vessels after an injection of radio opaque substance is known as angiocardiology. Several types of apparatus are used. Manually operated X-ray film cassette changers have the disadvantages of inaccurate timing and slow speeds (rarely two pictures per second may be obtained), mechanical cassette changes allow a more rapid sequence of film exposures but cinematography provides a more continuous picture of the passage of dye through the heart and will probably replace other methods. Oblique or lateral views are often necessary, but it is desirable to eliminate a second injection of dye by some form of simultaneous two plane cassette changer. The radio opaque substance which is most widely used is 70 per cent diodone. The dye is injected through a wide bore needle or catheter to facilitate a rapid injection, which should take less than 2 seconds. Forty to 50 ml are required for adults and 10 to 30 ml for children. The dye is non toxic in these doses. The patient should be recumbent. All children should be anaesthetised and there is much to be said for using a general anaesthetic in adults. The procedure is not without risk and the overall mortality is approximately 0.5 per cent, but most of the deaths have occurred in severe cyanotic congenital heart disease.

The normal angiocardigram shows the right heart chambers as a "U"-shaped curve, and on the right side the column of dye in the superior vena cava is seen entering the right auricle, and in the centre the tricuspid valve may sometimes show as a notch. On the left side of the "U" lies the right ventricle, a ragged chamber, the size of which will depend on whether the picture is taken in systole or diastole. The pulmonary outflow tract is well seen towards the periphery of the cardiac silhouette at the base of the right ventricle, as the terminal portion of the "U". The main pulmonary artery does not form the pulmonary arc. In the left anterior oblique view, the superior vena cava is superimposed on shadows of right auricle and right ventricle, which are seen anteriorly. The pulmonary artery curves backwards, forming an arch, the terminal downstroke of which is formed by its left main branch. The bifurcation of the pulmonary artery is usually seen about the centre of the arch. The pulmonary arteries and veins are well seen in both anterior and oblique views. In the anterior view, the pulmonary veins are seen draining into a central oval opacity, which is the left auricle. Superimposed upon the auricle is the base of the left ventricle, the apex of the ventricle projects downwards to the left. The left ventricular cavity varies considerably in size with the phase of the cardiac cycle. The root of the aorta is obscured in the cardiac shadow, but the dye filled aortic arch is seen above it. The chambers of the left heart are best seen in the left anterior oblique view where the left auricle is seen above the shadow of the left ventricle. The aorta arises almost in the centre of the cardiac shadow and arches antero posteriorly. At the origin of the aorta which is deep in the heart shadow, the sinuses of Valsalva appear as a bulbous dilatation. In the normal adult the progress of the dye through the right heart and pulmonary arteries is seen in pictures taken between $\frac{1}{2}$ and 4 seconds after the beginning of the injection of dye, and that through the left heart and aorta is seen in pictures taken after 6 seconds.

Angiocardiology can show abnormal anatomy of the heart chambers and great vessels and if the passage of the dye is recorded with sufficient continuity some aspects of the dynamics of the circulation may be studied. Angiocardiology is especially valuable in congenital heart disease where shunts from the right to the left side are shown by premature opacification of the "left side", but shunts in the

reverse direction are not readily seen. In addition, the size, position and abnormalities of the aorta and its branches may be seen, information which is of value to the surgeon when planning operations for coarctation of the aorta or anastomotic operations for the treatment of cyanotic congenital heart disease. Aneurysms of the great vessels may be distinguished from other masses in the mediastinum.

CARDIAC CATHETERISATION.—Three kinds of information can be obtained by means of cardiac catheterisation—(1) pressures may be measured in the right heart and the pulmonary artery; (2) samples of blood for gas analysis may be obtained from these sites; and (3) by means of X-ray screening the passage of the radio-opaque catheter may reveal abnormal channels and heart chambers. Cardiac catheterisation is safest and likely to provide the most useful information when carried out by an experienced team comprising an operator, with one assistant and technicians.

Technique.—The plastic catheter is very flexible, radio-opaque, and has a slight curve a few centimetres from the tip: it is filled with heparinised saline from a 10 ml. syringe attached by an adaptor. The tip is introduced into the cubital vein which has been exposed and opened by a small cut after adequate infiltration of the skin and surrounding tissues by a local anæsthetic. Subsequent manipulations of the catheter should be checked by X-ray screening. The catheter is gently manoeuvred up the arm vein to the thoracic inlet where it curves into the superior vena cava to gain the right auricle. By various manoeuvres the operator may now move the catheter through the tricuspid valve to the right ventricle, the pulmonary artery and its branches. If observations on the pulmonary capillaries are required, the catheter may be pushed into the smaller lung vessels to the point of blockage.

Blood samples are withdrawn through the catheter at various points and preserved under paraffin for gas analysis with a Haldane or Van Slyke apparatus. Pressures should be measured by means of an electromanometer and an adequate device for recording graphically the pulse pressure curves.

Applications.—The cardiac output may be calculated from the Fick principle as follows: cardiac output (litres per minute) = $\frac{\text{total oxygen consumption in ml. per minute}}{\text{mixed venous blood in ml. per litre} - \text{oxygen saturation of arterial oxygen}} \times 10$. Oxygen consumption is obtained by means of a spirometer, arterial samples are obtained by femoral artery puncture, and samples of mixed venous blood from the pulmonary artery by catheterisation.

Intracardiac shunts may be detected by obtaining blood samples of high oxygen saturation from the right heart and pulmonary artery, e.g. in the septal defects and patent ductus arteriosus. X-ray visualisation of the passage of the catheter through these channels into the left heart or aorta is of diagnostic importance when the shunt is in the reverse direction.

Pressure measurements and pressure curves help in the diagnosis and assessment of various conditions, especially pulmonary hypertension and pulmonary stenosis. In right heart failure the diastolic pressure in the right ventricle is raised and this is reflected in a general elevation of pressures in the right auricle. Cardiac catheterisation has provided much information during the past decade concerning the hæmodynamics of heart disease. Diagnosis is now more accurate and the indications for cardiac catheterisation are diminishing and are largely confined to the obscure forms of congenital heart disease.

CIRCULATORY FAILURE

In circulatory failure the body receives an inadequate supply of blood. There are two forms, one is acute, causing shock or syncope, and is sometimes due to heart disease but often to extracardiac causes; the symptoms are mainly due to low cardiac output and systemic arterial hypotension. The second form, generally known as heart failure or congestive heart failure, is almost always due to cardiac

disease; the clinical picture is largely the result of secondary and compensatory effects of a chronic inadequate cardiac output, with the maintenance of a relatively normal blood pressure.

HEART FAILURE

The ultimate cause of heart failure lies in the physiology of heart disease, but the clinical causes of heart failure include all the known forms of heart disease. More than one cause is often present—thus systemic hypertension and myocardial disease often coexist, whilst rheumatic valvular disease is often accompanied by active rheumatic myocarditis. The causes of heart failure may be classified as follows:

① Primary myocardial disease (e.g. inflammation, ischæmia, etc.). ② Increased resistance to systolic ejection (e.g. hypertension). ③ Increased stroke volume (e.g. aortic incompetence, mitral incompetence). ④ Increased heart rate (e.g. prolonged tachycardia in infants). Generally loads due to increased volume are tolerated better than those due to increased pressure, and tachycardia is tolerated extremely well, but persistent high rates operative over a long period may lead to failure.

The essence of heart failure lies in the inability of the heart to deliver an adequate blood supply to the tissues under all circumstances. In other words the cardiac output is inadequate and fails to meet all requirements of the individual. The site of this failure may be primarily located in one or other ventricle or in the heart as a whole. Lewis emphasised that the level of cardiac output as a measure of circulatory efficiency is significant only when considered in relation to the demand on the circulation, e.g. in thyrotoxicosis or anæmia the cardiac output required for adequate oxygen transport at rest may be double that of the normal subject.

Under physiological conditions the heart responds to increased venous filling by a greater liberation of energy and increased output. At the level of the muscle fibre this means that increased stretching, resulting in increased surface area, results in more powerful contraction; more energy is stored in diastole and more is liberated on contraction. The isolated muscle strip or heart-lung preparation responds in this way up to a critical point beyond which a further load results in a diminished response (Starling's principle). This critical point is never reached in healthy man, but in heart failure it is reached and passed; there is then an inadequate systolic ejection into the great vessels, some blood is retained in the chambers and dilatation and hypertrophy follow. Compensatory hypertrophy is a long-term adaptation to these adverse factors. The diastolic filling pressure rises and auricular contraction becomes more forcible. Up to a point output may be restored but ultimately this is permanently reduced. The difficulty of deciding what is cause or consequence dominates all the problems in heart failure. It is still not certain whether venous hypertension behind the failing chamber is a merely passive phenomenon or whether it is positive and compensatory. Hæmodynamic changes occur very rapidly and an unstable equilibrium is soon established, so that the exact sequence of events is difficult to analyse.

Corvisart (1812) considered that the clinical phenomena of heart failure were due to the increased size of the heart pressing on the lungs and obstructing the circulation. Hope (1830) introduced the back pressure theory which has been elaborated and maintained to the present day. Starling's work with the heart-lung preparation appeared to support the back pressure theory but it should be remembered that there is no chronic dilatation or hypertrophy in the heart-lung preparation, no long-standing œdema and no elaborate system of reflexes in the central nervous system and clinical heart failure is a relatively chronic process, often lasting years. In the back pressure theory venous congestion is paramount in the formation of œdema; but there is now much evidence to show that œdema formation depends on other factors. Mackenzie and Lewis assumed that the inadequate blood supply to the organs was

the important abnormality this theory of forward failure is supported by modern researches, but the older theories cannot be abandoned lightly. It is probable that neither theory explains all the facts.

In all forms of heart failure the cardiac output is subnormal at rest in the late stages but in the early stages output may be normal at rest and only inadequate during exercise. In other words the cardiac reserve is diminished. An inadequate supply of blood results in its redistribution in the circulation as a whole. There is some evidence to show that the fall in renal blood flow is selective and relatively greater than the fall in cardiac output. Lowered renal blood flow results in diminished glomerular filtration and greater tubular resorption of water and salt this appears to be a vital process and under circumstances other than congestive heart failure the mechanism has homeostatic features. The retention of water and salt leads to haemodilution, hypervolaemia and ultimately an increase of extravascular fluid volume and the accumulation of oedema. Oliguria results from the retention of water and urine analysis at this time shows a falling salt content. Man's habitual high intake of sodium chloride is of no consequence when renal excretion is normal and unlimited but in heart failure a deteriorating situation is potentiated. Hydrostatic factors, increased capillary permeability, increased accumulation of tissue metabolites and malnutrition probably also play a part in accumulation of oedema. Whatever the true importance of the various factors in heart failure the importance of salt retention is emphasised by the remarkable improvement which may be achieved by salt depletion using dietetic, diuretic or ion exchange methods. Any mechanism causing further salt retention aggravates heart failure.

Venous hypertension is the most important sign of heart failure. It is possibly due to a reflex venopressor mechanism together with increased circulating blood volume but when venous hypertension occurs behind an insufficient or stenosed auriculo-ventricular valve this seems to be a true backward effect. In the early stages of failure and in high output states it is possible that systemic venous hypertension is compensatory but later the adverse effects of increased venous hypertension in heart failure are shown by the effects of the recumbent posture and by blood transfusion whilst the beneficial effects of a reduction in venous pressure are shown by venesection and change from a lying position to a more upright one. The elevation of systemic venous pressure in heart failure is responsible for the distension of the liver which must be considered of secondary importance. Even here there is some evidence that the damage to liver cells is the result of diminished blood flow rather than venous congestion.

When heart failure arises primarily on the left side pulmonary venous hypertension develops. This is probably due to a temporary imbalance between the output of the left and right sides of the heart and this state is adversely affected by fluid retention. Pulmonary arterial pressure also rises in left heart failure and this is probably a direct consequence of the pulmonary venous congestion. Pulmonary oedema occurs when hydrostatic pressure in the capillaries exceeds the osmotic pressure of plasma. Dyspnoea is the most common symptom of heart failure and results from pulmonary congestion, cardiac dilatation which further reduces vital capacity and an increased sensitivity of pulmonary reflexes.

There are many variable factors in the mechanisms which determine the passage from a normal circulation to one of unresponsive congestive heart failure and no one theory at present explains all of the facts. It appears that the clinical picture is produced by a series of relatively slow and only partially adequate adjustments to the diseased heart.

Clinical Features.—From the clinical point of view it is convenient to assess cardiac failure in terms of left-sided heart failure and right ventricular failure. Both conditions occur as isolated phenomena or they may appear together, or more often right-sided failure follows left after a variable period when it is more satisfactory to

use the general term congestive heart failure. Whilst most cases of left heart failure are due to ventricular failure, it should be noted that in pure mitral stenosis the left ventricle is unaffected, although the clinical picture is left-sided in the early stages.

LEFT VENTRICULAR FAILURE.—Dyspnoea refers to the distress accompanying increased effort in breathing. It is the essential symptom of left heart failure. Cough is also common and is sometimes accompanied by hæmoptysis. Every grade of dyspnoea is encountered from the first detectable departure from physiological dyspnoea on effort to severest degrees which occur at rest and restrict all effort. Acute phases of dyspnoea, not necessarily provoked by effort, are common and range from orthopnoea, mild cardiac asthma, mild and severe paroxysmal nocturnal dyspnoea to pulmonary oedema.

At first effort dyspnoea occurs only with the more severe exertion; it is often only possible to detect a departure from the physiological by careful interrogation. Gradually the threshold of effort producing dyspnoea is lowered. It is often worse later in the day; undressing may provoke breathlessness, but a night's rest brings relief in the morning. Sooner or later breathlessness is present at rest and readily increased by speech, emotion and the slightest effort. Breathing is shallow, quick and obviously troublesome, being accompanied by much effort. It is never sighing and deep and is not relieved when attention is diverted. Obesity and diffuse pulmonary disease may produce a similar picture but it is rarely as severe. Orthopnoea commonly appears early in left heart failure. Here recumbency causes an increase of dyspnoea which is relieved by sitting or standing up. These patients sleep propped up by pillows or even prefer to spend nights in an armchair. It occurs in mitral stenosis and bronchial asthma as well as in patients with left ventricular disease.

Paroxysmal cardiac dyspnoea.—Paroxysmal dyspnoea and cardiac asthma are synonymous. Although often occurring before effort dyspnoea and orthopnoea have appeared, paroxysmal attacks usually arise later in the natural course of the disease and they may be of any degree of severity. Most attacks occur at night and it is probable that change in posture to a more horizontal level is the immediate cause, although there is often a history of an anxiety dream immediately before the attack. A particularly strenuous day's work, large meals and a greater salt intake during the preceding day may be factors which precipitate an attack during the night. Attacks commence with a sense of suffocation and dyspnoea. The patient is compelled to sit up or often to get out of bed. Characteristically patients seek an open window. There may be a sense of constriction in the chest, cough, and the expectoration of blood-tinged watery mucus. Breathing may become extremely difficult, wheezy and accompanied by very great distress. Relief is mostly spontaneous and usually occurs within an hour. Anxiety is an especial feature of nocturnal attacks and the pressor response accompanying this probably increases the severity and duration of the attacks. Pulmonary oedema constitutes a more severe and acute stage of left ventricular failure. Dyspnoea is worse and there is often precordial pain, respiration is noisy and accompanied by coughing and expectoration of much watery mucus which is often pink with blood. Cyanosis develops from asphyxia caused by the transudate. Mental confusion may supervene and sometimes there is amnesia after the attack. After the pulmonary congestion has subsided, there is usually no deterioration in the patient's condition. Cough is a common symptom accompanying dyspnoea at any stage of left heart failure. Occasionally it is the dominant symptom and leads to erroneous diagnosis. Hæmoptysis and staining of sputum occur commonly with the severe forms of congestion. Occasionally a large hæmorrhage occurs.

Signs.—Examination of the lungs may show the presence of adventitious sounds ranging from fine basal crepitations in the early stages, to extensive coarse crepitations over all of both lung fields in pulmonary oedema. The intensity of these signs parallels the level of dyspnoea. Unilateral or bilateral hydrothorax as shown by diminished air entry and dullness to percussion may occur in pure left heart failure. The pleura is

drained by the pulmonary veins as well as the systemic circulation. However, pleural effusions are more common in combined right and left heart failure. *Cheyne Stokes respiration* frequently occurs in the late stages of left ventricular failure, especially in the elderly. Periods of heightened respiration alternate with depressed respiration or even apnoea. Examination of the heart may reveal the underlying cause of the heart failure e.g. aortic incompetence, but of greater importance in relation to the question of heart failure *per se* is the presence of triple rhythm (or gallop rhythm) 'Gallop' rhythm. This is due to the addition of a third sound, similar in timing and quality to the third heart sound heard in children and young adults. It is intimately related to ventricular filling—it may be that filling becomes audible under the impact of auricular hypertension and in the presence of damaged ventricular muscle. It is heard as a low pitched sound shortly after the second sound, it is most easily heard at or near the apex, and when using a bell type stethoscope. These low pitched vibrations can often be palpated and perhaps more often seen. If the apex is observed from one side, then the lift of systole may be seen to be followed by a small after wave, coincident with the third heart sound. Tachycardia commonly accompanies heart failure. It will be readily appreciated that as diastole shortens with the increased heart rate the third sound will approach the first heart sound, it may coincide with the sound of auricular systole which is thereby augmented and the gallop sound now appears late in diastole, giving rise to presystolic or summation gallop rhythm. Thus the essential feature of these triple rhythms whatever the apparent cadence, is the addition of a filling sound. In some patients with early left ventricular failure the augmented systole of the hypertensive aortic can be appreciated by the presence of a loud auricular sound.

Cardiac enlargement accompanies heart failure. Left ventricular enlargement due to hypertrophy may be recognised by the apex which develops a sustained heaving character. As failure and dilatation increase the apex beat becomes more diffuse and loses some of its force. These qualities of the beat are more important than its position in the chest. Murmurs are of no consequence in the diagnosis of heart failure but a systolic murmur often develops with increasing cardiac size and is due to functional incompetence of the auriculo ventricular valves.

During attacks of left ventricular failure (cardiac asthma, pulmonary oedema) the blood pressure is elevated, and there may be alternation of the pulse which is best detected by using the sphygmomanometer but may be felt at the radial pulse. Weak beats alternate evenly with the strong, this sign should not be confused with bigeminal pulse where the weak ectopic beat is close to the preceding strong beat. In attacks of left ventricular failure there is often intense peripheral constriction shown in pallor of the skin and coldness of the extremities.

Patients with great left ventricular enlargement occasionally present with the picture of right ventricular failure and are able to lie flat. This is said to be due to mechanical embarrassment of the right ventricle through bulging and hypertrophy of the interventricular septum which prevents the development of lung congestion (Bernheim's syndrome).

RIGHT VENTRICULAR FAILURE—The commonest cause of right heart failure is pulmonary hypertension and congestion due to left heart failure. Dyspnoea is therefore a prominent symptom in congestive heart failure but its severity and paroxysmal nature tend to subside when right heart failure supervenes. In the relatively uncommon condition of pure right ventricular failure dyspnoea is not a prominent feature although it may be severe when parenchymatous lung disease is responsible for the right heart failure. Patients with pure right heart failure do not have orthopnoea and are often able to lie flat.

Fatigue and exhaustion are common symptoms in congestive heart failure. Fatigue becomes a more prominent symptom when dyspnoea is relieved by the development of right heart failure and tricuspid incompetence. Generally dyspnoea is more in

capacitating and unpleasant for the patient, so that fatigue is not noticed because of the limitations imposed by dyspnoea. Discomfort in the right hypochondrium from hepatic congestion is often present; it may become severe after effort and is rather slowly relieved by rest. This hepatic pain is not infrequently mistaken for gastro-intestinal disease. Anorexia usually accompanies congestive heart failure, nausea and vomiting sometimes follow; similar symptoms are sometimes caused by digitalis or morphine rather than the heart failure.

Severe heart failure may cause temporary amnesias and slight confusion, but the more serious psychotic reactions are rare. Slight jaundice is often present and is due to hepatic congestion or to hæmolysis following extensive pulmonary infarction. Cardiac cirrhosis occurs in 2 to 5 per cent. of patients with heart disease and especially when there is chronic congestive heart failure with tricuspid incompetence.

Signs.—Systemic venous hypertension with congestion of both venæ cavæ and their tributaries invariably accompanies right heart failure. The appreciation of raised jugular venous pressure is the most important sign of heart failure. A partial mechanical obstruction often leads to apparent congestion of the external jugular vein which is thus unreliable for estimating central venous pressure and it should not be used unless a free venous pulse is seen. Pulsation of the internal jugular veins can be seen when there is heart failure with the patient reclining at an angle of 45°. The height of the venous pressure should be measured from the sternal angle. When the pressure is very high, congestion of veins is obvious even in the periphery. The recognition of jugular venous hypertension is difficult when there is tricuspid valve disease (see p. 877). In tricuspid incompetence a large "cv" wave rises in the neck with each ventricular systole; although this is often associated with congestive heart failure, it is not necessarily so. Hepatic tenderness and enlargement should be sought. Careful palpation of the abdomen usually reveals hepatic enlargement in congestive cardiac failure; systolic pulsation of the liver occurs when there is gross tricuspid incompetence. Gentle firm pressure over the liver will cause a further elevation of the jugular venous pressure; this manœuvre may aid in the determination of the height and form of the venous pulse wave.

Oedema occurs in the dependent parts, at the ankles of ambulant patients, and over the sacrum, at the backs of the thighs and in the genitalia of bed patients. It is usually symmetrical—a gross difference between the degree of oedema of the ankles may indicate the presence of a local vascular lesion, particularly phlebo-thrombosis. Other manifestations of the dropsical state are pleural effusion, pericardial effusion and ascites. Oliguria and increased weight parallel the accumulation of oedema, and diuresis with a fall in body-weight is a good guide to the effectiveness of therapeutic measures. Cyanosis is not an essential feature of heart failure, although peripheral cyanosis from peripheral arteriolar constriction and stasis is often the result of low cardiac output; the hands, feet, tip of the nose and lobes of the ears are cold and blue, but the arterial blood is normally saturated with oxygen. Central cyanosis, when present, is related more directly to the underlying cause of heart failure: there are two causes—pulmonary disease producing anoxæmia, and congenital heart disease causing central mixing of the venous and arterial blood streams. Central cyanosis is more generalised and the blueness is as obvious in the mouth, tongue and retina as in the periphery. Arterial oxygen saturation is subnormal.

Radiology of heart failure (see also p. 803).—All degrees of vascular congestion of the lungs occur. A slight increase in the density and enlargement of the hilar shadows is found in early left ventricular failure; later the congestion extends to the peripheral lung fields. A soft diffuse haze which blurs the outline of hilar vessels extends out for a variable distance and is due to oedema. In pulmonary oedema massive shadows extend from the hilar regions over the mid zones of the lung (resembling the wings of a butterfly); the apices and bases are normally clear in acute pulmonary oedema. In left ventricular failure small effusions may appear at the bases

and in the interlobar fissures, and large effusions are commonly seen in congestive heart failure. Wedge shadows, linear shadows and other local opacities often show the presence of pulmonary infarction. The heart shadow is usually enlarged in heart failure and there is widening of the superior mediastinum due to distension of the great veins. Changes in the contour of particular cardiac chambers largely depends on the underlying disease which is responsible for the heart failure.

Urine analysis—Oliguria is related to the severity of heart failure. Urine is concentrated but the sodium chloride content is low. Slight albuminuria is usually present. *Blood chemistry*. Sodium and chloride ions tend to be subnormal but plasma potassium is usually normal. Blood urea may be moderately raised when urine output is low. Gross deviations of blood chemistry may be associated with excessive therapeutic salt depletion (see pp. 416, 816). *The erythrocyte sedimentation rate* is slowed in heart failure and is therefore not a reliable guide to the course of rheumatic carditis, bacterial endocarditis and other infections in the presence of heart failure.

TREATMENT OF HEART FAILURE.—Heart failure presents a clinical picture of varying severity which is largely independent of its underlying cause. Likewise the treatment of heart failure follows general principles which may be applied independently of the cause. Firstly the work of the heart must be reduced by physical and mental rest. Secondly the force of the heart beat should be improved by the use of digitalis and thirdly the tendency to accumulate water and salt should be treated by diuretics, low salt diet and occasionally by the mechanical removal of fluid. Treatment of the underlying cause of heart failure is of fundamental importance, but this is rarely possible. However in some conditions, such as mitral stenosis, thyrotoxicosis and anæmia, the cause may be removed or profoundly modified and this is described in the appropriate sections.

Rest.—Physical and mental rest diminishes cardiac work and is the most important therapeutic measure in cardiac failure. The duration and degree of rest required for any patient depends on the severity of the illness. A single attack of cardiac asthma may require little more than a few days in bed, whilst 2 or 3 weeks of partial bed rest is advisable for the mildest cases of congestive heart failure; such patients should be allowed up for toilet purposes. In more severe degrees of congestive cardiac failure bed rest in a semi-upright position (obtained by pillows, a back rest or a special cardiac bed) should be maintained for at least 3 weeks or until the signs of congestion have subsided. Most patients may be allowed to move about in bed, feed themselves and receive visitors, but it is occasionally advisable to restrict all activities; continuous nursing care is then required. Mental rest should be promoted by reassurance, explanation and the use of sedatives.

Thrombosis in the deep leg veins with subsequent pulmonary infarction are hazards of prolonged strict bed rest in any condition, but they are especially common in patients with heart disease. Some physicians have advocated an armchair régime to overcome this and the other adverse features of bed rest; the armchair position is good from the physiological point of view, but patients are tempted to increased physical activities and it seems best to reserve the armchair for a stage after a period of initial bed rest.

The important considerations in deciding the mode of rest and its duration are the severity of circulatory failure and the patient's general physical and mental state, the domestic and economic circumstances of the patient usually determine the availability of nursing help and therefore the advisability of home or hospital treatment. It is better to err on the side of too little than too much rest in elderly patients, especially when the condition of the heart is such that little improvement can be expected. When some degree of ambulation has been permitted throughout, the transition to convalescence is facilitated.

Diet.—One of the advantages of bed rest is that food requirements are less, so

that cardiac work is further diminished. In severe heart failure anorexia limits food intake, but in other cases meals should be small and as attractive as possible, with a maximum daily intake of 1000 calories during the initial rest period. A low salt diet is a most effective method of relieving the symptoms of heart failure. Dietary sodium should be reduced to 500 mg a day, but this is not always possible for psychological, gustatory or domestic reasons, it is impossible in unintelligent or unco-operative patients outside hospital and attempts to reduce sodium should be abandoned in favour of other methods of producing hyponatremia. It is not easy to achieve levels of 500 mg of sodium daily and probably most patients on a well managed low salt regime receive nearer 1 g. All food must be prepared and served without the addition of salt or soda. Foodstuffs must be carefully selected, bearing in mind that most protein foods (milk, eggs and red meat) have a relatively high sodium content. Certain proprietary foods high in protein and low in sodium are available if it is necessary to augment protein intake. The following rules should be observed: (1) Use salt free bread (obtainable from many bakers), salt free butter or margarine (if not obtainable it may be prepared by washing free of salt), salt free fat or arachis oil for roasting and frying purposes. (2) Use plain flour and a special baking powder containing potassium bicarbonate instead of sodium bicarbonate for cakes, puddings and scones, which may help to vary the diet. (3) Restrict milk to half a pint daily and eggs to one per day. (4) Avoid the following foods with a high salt content: ham, bacon, sausages, tinned meat, meat extracts, smoked and salt fish, tinned fish, cheese, pickles, tinned vegetables and soup, chocolate, junket and dried fruits (except prunes). (5) Use vinegar, mustard, pepper and sodium free salt substitutes for seasoning purposes. There is no necessity to restrict fluids on a low salt diet, water, tea, coffee and alcohol are allowed. Beer contains from 75 mg to 130 mg of sodium per pint. Many patients find that a low sodium diet is flat and monotonous, particularly in the first weeks of treatment, but most consider these unpleasant features worth while after experiencing relief from distressing symptoms. There are often difficulties in obtaining a regular low salt diet, especially for those who must feed in canteens and restaurants.

A diet of rice, sugar, fruit and water is worthy of trial in patients with intractable congestive heart failure, and especially where hypertension is the cause. Few patients keep to the diet for more than a few weeks, thereafter they are often happy to receive an otherwise unpalatable low sodium diet which may effectively maintain any improvement initially achieved by the rice diet. Obesity, which is almost invariably due to chronic habitual overeating, should be corrected in patients with heart failure by an appropriate drastic reduction in the calorie value of all food.

Tobacco should be discouraged except where its withdrawal causes much mental stress. Alcohol is permitted in moderation, it is a satisfactory sedative and diminishes anxiety. An ounce or two of whisky at night promotes sleep, and a glass of champagne may elevate morale and create a sense of well being during the day.

Drugs—*Morphine* may be used in all forms of heart failure except in pulmonary heart disease where its depressing effect on a sensitive respiratory centre may be fatal. Morphine is the drug of choice in acute left heart failure. It allays anxiety, reduces mental and physical tension, secures sleep and possibly causes a fall in venous pressure—all factors which tend to diminish cardiac work. Most patients with heart failure tolerate morphine well. It is better to err on the side of large doses than in inadequate ones and the drug should never be withheld when there is great distress in terminal heart failure. If as in acute left ventricular failure, morphine is required urgently, it may be given intravenously (gr. $\frac{1}{4}$ in 5 ml saline) but otherwise oral or subcutaneous doses (gr. $\frac{1}{4}$ to $\frac{1}{2}$) are effective and may be repeated in 2 hours if there is no improvement.

Digitalis—Withering published his *Account of the Foxglove and Some of Its Medical Uses* in 1785. Digitalis is still the most important drug in the treatment of heart

failure. Many preparations are available and the pharmacological effects of the whole leaf or any of the glycosides are similar.

Mode of action—It is reasonably certain that the beneficial effects of digitalis are mainly due to a direct action on heart muscle causing stronger contractions. An increased cardiac output and elevation of arterial tension follow, whilst congestion and high pressure in the venous or filling side of the heart are reduced. It is probable that a less important peripheral action also tends to lower the venous pressure. Digitalis also causes a beneficial slowing of the heart, particularly when there is tachycardia associated with heart failure and auricular fibrillation. Slowing is effected by direct central vagal stimulation and by a depression of the intracardiac conducting tissues. It is probable that even this slowing effect is largely due to a direct myocardial action which causes stronger contraction and increased refractoriness during recovery. Furthermore, as the cardiac output improves, reflex vagal action also causes slowing. Improvement of the circulation leads to a reversal of all the adverse factors accompanying heart failure. Thus renal blood flow is increased and diuresis follows. Congestion in the lungs subsides, heart size diminishes and vital capacity increases. All other organs, including the liver which becomes smaller, are relieved of congestion and there is a fall in circulating blood volume. Variability of response to digitalis has long been a matter for speculation and research. It appears that the best effects are achieved when failure is accompanied by a normal or low output and venous congestion, and less effect is obtained where the congestion of failure is largely compensatory and the cardiac output is normal or high.

Administration—In most cases of heart failure it is advisable to obtain the greatest optimum effect of digitalis as soon as reasonably possible by giving large initial doses (digitalisation). This may be achieved very rapidly by the intravenous route, but in most cases the oral method is satisfactory and it is safer. After digitalisation the blood levels of digitalis are kept up (and hence the effectiveness of the drug) by smaller maintenance doses.

The powdered leaf of digitalis purpurea (digitalis folia B.P.) is the most widely used preparation for oral use. Tablets contain gr 1 (or gr $1\frac{1}{2}$) and digitalisation may be effectively carried out by giving on three successive days gr 3 t.d.s., gr 2 t.d.s. and gr 1 i.d.s., gr 1 to 3 daily is usually required for maintenance. An alcoholic solution of the leaves of digitalis purpurea (unctura digitalis B.P.) has no advantage over the tablets and doses are more likely to be inaccurate. Bio assay is necessary for standardisation. Relatively pure glycosides of digitalis purpurea (digitoxin and Nauvella's digitaline) are available, but are not widely used in Great Britain. These glycosides may be standardised by weight and potency is relatively constant, but they are slow to act and elimination is prolonged. Local gastric irritation is less than with the whole leaf preparations.

Digoxin is a glycoside obtained from the leaves of digitalis lanata, it should not be confused with digitoxin from *D. purpurea*. It is a pure substance and can be standardised by weight. Tablets contain 0.25 mg and the daily maintenance dose is usually 0.5 mg. Rapid digitalisation usually requires from 2 to 4 mg in 24 hours. It is available for intravenous use. One ml contains 0.5 mg of drug and this should be administered slowly after appropriate dilution. Lanatoside C is also derived from digitalis lanata, it acts quickly and excretion is very rapid, it may be given by mouth or intravenously.

Ouabain (strophanthin) is derived from strophanthus gratus and is usually reserved for emergency intravenous use. Its action and excretion are very rapid and digitalisation should be maintained with a slower acting oral preparation, 0.5 mg should be injected slowly in the first instance.

Digitalis is indicated in all forms of heart failure whatever the cause and whatever the rhythm. It is equally useful in cases of left heart failure and in those of congestive right heart failure, but the degree of therapeutic response varies and depends on many

factors, the most important of which is the underlying cause. Great care should be exercised if it is used in the presence of recent myocardial damage, *e.g.* in recent cardiac infarction or rheumatic carditis, when other drugs should be tried first, and it should never be used in diphtheritic carditis. Digitalis may be used with caution in the presence of heart block if failure supervenes, and is unresponsive to other drugs. Intravenous digoxin or ouabain have a pressor effect and are best avoided in acute left ventricular failure.

Overdosage of digitalis—The first and most common symptom is anorexia, which may progress to nausea and vomiting. Difficulty arises when these symptoms may be due to continuation of congestive cardiac failure. Extrasystoles are the most common cardiac sign of overdosage; they frequently follow each regular beat, producing pulsus bigeminus (coupled beats). Digitalis should then be omitted for 1 day and thereafter reduced, but there is no necessity to change the form of digitalis or stop it altogether. Extrasystoles occurring before treatment is started are no contraindication to digitalis. With more serious intoxication multifocal ventricular ectopic beats may be so frequent as to cause tachycardia, paroxysmal ventricular tachycardia may appear, and even ventricular fibrillation. Excessive slowing of the heart is a common sign of digitalis overdosage. The vagal action of digitalis causes sinus bradycardia and even sinus arrest; nodal rhythm may appear and complete auriculo-ventricular dissociation has been observed.

Digitalis causes profound changes in the electrocardiogram which may be indistinguishable from those produced by disease of the myocardium. These effects should not be regarded as an indication to reduce dosage for they are routine when a therapeutic effect is obtained and may occur when the heart is normal. The S-T interval is lowered and may become slightly coved, but it is more often depressed in a straight sloping form. The T waves may be blunted, lowered or even inverted. The PR interval may be prolonged and in more serious levels of intoxication depressed conduction with or without extrasystoles may be seen.

Diuretics—The organic mercurial compounds are the most effective diuretic agents available at the present time and they are now widely used. Other diuretics such as urea, hypertonic solutions, acidifying agents, xanthines and uracil compounds which have been used in the past are not indicated in heart failure.

The organic salts of mercury are more soluble and less toxic than inorganic ones, but their action is the same. Therapeutic doses of injected organic mercurials are rapidly cleared from the blood through the kidneys and the protein bound circulating mercury does not diffuse into other tissues; excretion in the urine continues over a prolonged period. There is considerable evidence that therapeutic mercury acts by causing slight reversible damage to cells of the lower nephron (large toxic doses produce necrosis of tubular cells). This tubular damage results in the selective rejection of certain electrolytes, of which sodium and chloride are blocked to the greatest extent. Water excretion follows as an osmotic effect of the increased electrolyte content of glomerular filtrate. Urine volume increases within 3 hours and the diuresis persists for 12 hours, the magnitude of which depends on the state of the circulation, the dose, the rate of absorption of mercury, and on the degree of oedema. The overall effects are a reduction of excess sodium, reduction of oedema and blood volume with consequent improvement in heart failure.

Administration—Many preparations are available, mersalyl (Salyrgan), Neptal Novurit, Lisdione and Thiomerin. Intramuscular injection (2 ml) is satisfactory and safe and may be repeated in 5 to 7 days or sooner if there is much oedema and a good diuresis has been obtained with the first injection. It is usually safe to continue with a weekly injection for as long as required, but routine prescription should never be given without observation of the patient. Thiomerin may be given subcutaneously. Tablets for oral use and rectal suppositories are less effective than intramuscular or intravenous injection.

Indications—Organic mercurial diuretics are indicated in all forms of heart failure except when there is severe renal disease or a known sensitivity to mercury, it is not always necessary to use them when rest and digitalis are rapidly effective, but when œdema is gross a mercurial diuretic is always advisable. Early left ventricular failure responds well to mercurial diuretics and in this condition a weekly injection may prevent loss of work and loss of sleep from cardiac asthma. Mercurial diuretics are particularly useful when a low salt régime is not practical.

Toxic manifestations—Mercurials are relatively safe drugs, but a variety of untoward reactions may occur. The most important ill effects are those due to excessive diuresis and electrolyte depletion, they are likely to occur when mercurials are given frequently for long periods, especially when combined with a low salt diet. The resulting clinical states are often insidious and may readily pass undiagnosed or they are incorrectly attributed to heart failure. It is often possible to recognise one dominant pattern due to loss of a particular electrolyte, but mostly the clinical picture results from the disturbance of several factors. Weakness, malaise and apathy progressing to drowsiness are common symptoms, whilst headache, cramps, vomiting and confusion occasionally occur. By assessing the clinical state and blood electrolyte pattern it is usually possible to recognise one of the following:

- 1 *Hypochloraemia* is probably the commonest disturbance, but is less likely to occur when ammonium chloride is used with mercurial therapy. Alkalosis and uraemia may develop.
- 2 *Low salt syndrome* resulting from excessive excretion of salt and water may progress to acidosis and uraemia.
- 3 *Hypokalaemia* is rarely a significant factor. Tetany and vitamin deficiency have also been reported. These conditions should be corrected by administration of the appropriate ion and modification of the diuretic regime.

Chronic mercury poisoning (mercurialism) as shown by stomatitis, gingivitis, gastro enteritis and dermatitis, is not encountered with modern preparations. Acute hypersensitivity reactions, such as a transient skin rash with pruritus, are rare and mild but severe reactions may follow intravenous administration of the drug. Symptoms suggesting excessive digitalisation due to a mobilisation of digitalis from œdema fluid occasionally occur and are of little consequence.

Oxygen—In most cases of heart failure the oxygen content of arterial blood is normal. If, however, this is lowered because of pulmonary insufficiency, oxygen is indicated. Oxygen is of great value in patients with anoxic pulmonary heart disease (see pp 857, 1000) and when heart failure is due to other causes but complicated by pulmonary œdema, extensive pulmonary infarction or broncho pneumonia. Various methods of administration are available and selection usually depends on individual preference and available apparatus, however, an efficient oxygen tent is considered the most satisfactory.

Venesection lowers venous pressure and relieves congestion. It is of value in congestive heart failure whatever the cause, but mostly other therapeutic methods are preferred and it should not be used when there is anaemia or severe hypotension. It is most effective in cases of acute left heart failure and should be used more often in this condition. In patients with chronic right ventricular failure with great venous congestion which is responding poorly to drug treatment, a venesection may "break into" the vicious circle of failure and lead to a steady improvement with an increasing response to other drugs. 350 to 750 ml should be removed from the antecubital vein with a wide bore needle, using a sphygmomanometer cuff to increase the local venous pressure and enhance the flow. A similar effect to venesection can be produced by occluding the venous return from both legs by means of thigh cuffs inflated above the venous pressure but below the arterial pressure, symptoms may be relieved but they are likely to recur when the cuffs are released. This method is not advocated.

Acupuncture should be used to remove extensive œdema which is resistant to more usual therapy. The patient should be placed in an armchair position for 24

hours before puncture so that maximal accumulation of œdema occurs in the legs. Southey's tubes are introduced into subcutaneous tissues and small attached rubber tubes drain the fluid. An injection of 500,000 units of depot penicillin prevents sepsis which, however, should not occur if an adequate antiseptic technique has been used. *Paracentesis abdominis and thoracis*. Large effusions in the pleural sacs embarrass respiration and hinder recovery and should be removed by tapping.

SYNCOPE AND SHOCK

Syncope is a transient interruption of consciousness due to acute failure of the circulation, *shock* is a more protracted form of acute circulatory failure resulting in a depression of all vital activity and having characteristic clinical features. Systemic arterial hypotension is an essential feature of both conditions. These hypotensive states are sometimes referred to as peripheral circulatory failure, but this term is misleading because the whole cardio-vascular system is involved.

Arterial tension is the product of cardiac output and total peripheral resistance, changes in cardiac output are compensated by reciprocal changes in arteriolar tone so that arterial blood pressure remains relatively constant. When fall in cardiac output, whether of physiological or pathological degree, is incompletely compensated by peripheral constriction the resultant hypotension leads to syncope, shock or sudden death.

SYNCOPE

Syncope is usually brief, transient and totally reversible, but when serious trauma or disease is the cause, shock or sudden death may follow. The cause of unconsciousness is sudden arterial hypotension with resulting loss of support to the brain substance and cerebral anæmia. A fall in cardiac output is the initiating event in all cases, this may be physiological, as occurs in the upright posture, but may remain uncompensated by an unstable vasomotor nervous system (vaso-vagal syncope) or rarely the autonomic nervous system may be diseased (see below). In other cases a severe pathological fall in output may be due to hæmorrhage or heart disease (cardiogenic syncope) and remain uncompensated by relatively normal vasoconstrictor reactions.

VASO-VAGAL SYNCOPE (FAINTING)—Simple fainting is common and the clinical features are characteristic. The patient is usually in an upright posture and syncope is preceded by a feeling of "faintness", rapidly developing pallor, sweating and tachypnoea. Bradycardia accompanies the sudden fall of arterial pressure. Unconsciousness is brief, but rarely convulsions may follow. Recovery occurs when the patient is recumbent, there is no mental confusion after the attack and there are no abnormal signs in the nervous system. Pallor and bradycardia may persist for an hour.

Many interacting factors cause fainting, the more important ones are (1) the upright posture leading to venous pooling below the heart (functional hæmorrhage), increased by prolonged quiet standing and lumbar lordosis, (2) an instability of vaso-motor control leading to sudden vasodilatation in the muscles, (3) hot weather and a stuffy atmosphere which increase peripheral vasodilatation, (4) ill health—fainting is common during convalescence from illness, (5) psychic factors—intense emotional situations, fright and characteristically the sight of blood. Many subjects who have a tendency to recurrent fainting also show other features of psychoneurosis. Fainting is common in pregnancy, lumbar lordosis and the tendency to increased venous pooling below the heart are probably causal factors. In late pregnancy fainting may occur in the recumbent posture when a sudden fall in venous return may be caused by the uterus pressing on the inferior vena cava—equilibrium is rapidly restored by

turning to one side. Severe hæmorrhage commonly causes syncope which has similar features to other forms of vasovagal fainting.

Postural hypotension severe enough to cause fainting occurs when the sympathetic system is paralysed by bilateral sympathectomy, spinal anaesthesia and the ganglionic blocking of drugs of the methonium halide series; it also rarely occurs in association with certain chronic diseases of the nervous system such as tabes dorsalis and syringomyelia. A rare form of syncope occurs in middle-aged males where the essential feature of postural hypotension is associated with anhidrosis and impotence. Faintness comes on shortly after standing and the blood pressure falls steeply. Normal vasoconstriction is lacking, and the disease appears to be due to a gradually developing paresis of the sympathetic nervous system possibly originating in hypothalamic centres; once the disease has reached a certain degree, there is no further deterioration and fatalities have not been recorded. The *carotid sinus syndrome* is rare. The carotid sinus is hypersensitive and pressure upon it caused by movement of the neck, external pressure, or a tumour, may lead to profound hypotension and loss of consciousness.

CARDIOGENIC SYNCOPE.—A transitory sudden loss of consciousness is not uncommon in heart disease and it is due to a sudden fall of cardiac output. The usual premonitory symptoms of vasovagal syncope are absent and in most cases the attack comes without warning. There is usually pallor and, if unconsciousness is prolonged, convulsions may occur. Consciousness is regained without confusion and incontinence is rare. The causes are (1) a change of rhythm—syncope may occur at the onset of any arrhythmia, (2) heart block—see Stokes-Adams disease, p. 831, (3) very rapid ventricular rates, (4) cardiac infarction, (5) aortic stenosis, (6) aortic incompetence (rarely), (7) severe pulmonary hypertension, (8) severe pulmonary stenosis, (9) ball valve obstruction of the mitral valve. In aortic stenosis and in pulmonary hypertension syncope may be the result of effort, and in the latter condition it appears to be due to acute right ventricular failure. Effort syncope in heart disease should not be confused with the syncope which may come on after the cessation of effort in hot weather, when the cause is extreme muscle vasodilatation. Syncope due to ball valve thrombus in the mitral orifice is sudden, and produced characteristically by a change to the sitting or standing position; the prognosis is grave.

Treatment.—Attacks of syncope are terminated by lying flat. The treatment of recurrent fainting depends on the cause and is described in the appropriate section. Chronic postural hypotension is best treated by the sympathomimetic drugs given orally and at least four times daily; ephedrine (30 mg.) or amphetamine (5 to 10 mg.), or pædrene (20 mg.), or phenylephrine (5 to 10 mg.) should be tried and the most effective drug or combination of drugs selected.

SHOCK

The essential features of the shock state are arterial hypotension and a depression of all vital activities causing weakness, subnormal temperature, sweating and apathy. Consciousness is generally maintained without confusion, but syncope may occur. The skin is pale and cold, the arterial pulse is weak and rapid, and the venous pressure is low. Some patients are restless but most are quiet and lie still.

Ætiology.—The fundamental cause of the shock state, whatever the immediate cause, is a relatively acute severe reduction in cardiac output. Intense sympathetic action causing vaso-constriction follows and maintains the perfusion pressure of arterial blood, although at subnormal levels, to the head and other vital organs. The pallor and sweating is the result of compensatory sympatheticotonia. It is probable that many homeostatic mechanisms are operative in the compensation of shock; the sympathetic nervous system and adrenal medulla are responsible for vaso-constriction; selective renal vaso-constriction causing a reduction in renal blood flow is responsible

for fluid and electrolyte retention. Some degree of oliguria is always present in shock. If the shock state is prolonged it becomes irreversible and it is possible that the products of tissue anoxia are responsible for this.

The immediate causes of shock are severe external trauma and internal disasters to the major organs of the body. In the first category hæmorrhage, crushing and burning are important factors causing loss of fluid and a fall in circulating blood volume; pain and possibly the products of tissue damage exert a further depressor action. The second category includes perforation of the gut, peritonitis, pancreatitis, acute severe diarrhœa and vomiting, overwhelming septicæmia and massive pulmonary embolism, but damage to the heart itself by cardiac infarction and acute pericardial tamponade is especially likely to cause shock because there are not only the factors of pain and tissue damage, but also the direct reduction of cardiac output through damage to the pump.

Treatment.—Shock is a medical emergency, and treatment should be started as soon as the condition is diagnosed or before it occurs, if it can be anticipated. The immediate cause of the condition should be remedied if possible and as soon as possible, *e.g.* hæmorrhage should be stopped or a perforated viscus repaired.

The patient should be kept warm but not hot, and sufficient morphine should be given to stop pain. Hæmorrhage and all forms of traumatic shock are best treated by transfusion of blood, plasma or a plasma substitute such as dextran. Saline or glucose saline solutions are useful but not as effective. The newer vaso-constrictor drugs such as l-noradrenaline raise arterial pressure and should be used if there is no sign of improvement after a few hours (see p. 846). Cortisone appears to be effective in some cases, but its place in the treatment of shock is not yet established. *Prognosis* depends on the nature and severity of the underlying cause, the response to treatment and upon the duration of the shock state.

CARDIAC ARRHYTHMIA

INTRODUCTION

Myocardium has an inherent rhythmicity, but certain specialised areas become dominant foci of stimulus formation. All myocardium has the capacity to conduct these stimuli and cause excitation of adjacent muscle, but this function also is carried out by specialised tissue bundles. This section is concerned with disorders of the rate and rhythm of impulse formation and disorders of stimulus conduction over the rest of the heart.

The cardiac impulse arises in the sino-auricular node which is situated in the right auricular muscle near the entrance of the superior vena cava and it produces normal heart rhythm known as sinus rhythm. The artery to the sino-auricular node arises from a coronary artery, usually the right one, near its origin from the aorta. The rate of impulse formation depends not only on spontaneous rhythmicity but also on neurogenic and humoral factors. Sympathetic cardio-accelerator fibres and vagal inhibitory fibres have a dominant influence. The natural rate of impulse formation at the sinus node (70 per min.) is rather higher than the inherent rhythmicity of lower centres. Excitation from the node spreads rapidly over the auricles in all directions, inducing activity of the auricular myocardium which then stimulates the auriculo-ventricular node. This focus is in the auriculo-ventricular junctional tissues immediately to the right of the auricular septum, and is also influenced by the autonomic nervous system. Its own slower rhythm (60 per min.) is blocked normally by the higher frequency of the sino-auricular node. Conduction continues at a slower rate through the node and the ventricular muscle is reached by the bundle of His which divides into left and right bundle branches in the upper part of the

septum Each branch lies in the immediate subendocardium of the septum and subsequently breaks up into a network of fine conducting fibres (Purkinje fibres) which remain in the ventricular subendocardium. Excitation of the ventricular muscle appears to spread from the endocardium to the epicardium. The inherent rate of impulse formation of foci in the ventricular muscle is 40 per min., but these are blocked by the higher rate of stimuli from supraventricular centres. The arrhythmias may be classified in various ways. The following order is adopted here

- 1 Sinus rhythm
tachycardia, bradycardia, sinus arrest and phasic arrhythmia.
- 2 Ectopic beats and ectopic rhythm
auricular, nodal and ventricular
- 3 Tachycardias, paroxysmal and otherwise
paroxysmal tachycardia (auricular),
auricular flutter,
auricular fibrillation,
ventricular tachycardia,
ventricular fibrillation
- 4 Disorders of conduction

SINUS RHYTHM

SINUS TACHYCARDIA—Tachycardia means a fast heart rate. Normal resting rates lie between 50 and 90 beats per minute. In sinus tachycardia the increased rate is due to increased rhythmicity of the sinus node and this is largely due to diminished vagal tone or sympathetic stimulation. Sinus tachycardia merges imperceptibly from the physiological response to effort, emotion and digestion into the pathological, and tachycardia is only significant when considered in relation to its cause.

Ætiology—Tachycardia is found in all forms of heart failure, where it appears to be caused by the failure in some general way or by local damage to the myocardium. In some forms it may be compensatory in maintaining a higher than normal cardiac output but mostly it makes failure worse by diminishing the period of myocardial rest and recovery. Sinus tachycardia occurs in all conditions with a high cardiac output, such as thyrotoxicosis, arterio venous aneurysm, anæmia, beriberi and anoxic cor pulmonale. Here it is a factor in maintaining the high output. Tachycardia accompanies most infectious diseases, especially those accompanied by carditis.

Tachycardia may be caused by excessive use of tea, coffee, tobacco, alcohol or certain drugs, especially those affecting autonomic activity, e.g. atropine and adrenaline. Simple tachycardia is a common symptom in patients who are convalescent after prolonged illness. Psychoneurosis is a common cause of tachycardia especially when emotional disturbance is expressed through the cardio-respiratory system (see Cardiac Neurosis, p. 904).

Symptoms—Sinus tachycardia is mostly symptomless but sometimes patients are conscious of the rapid heart action.

Treatment is not indicated apart from that of the underlying cause.

SINUS BRADYCARDIA—Bradycardia means a slow heart rate. Some people have a naturally slow pulse and the well trained athlete may have a heart rate of 45 to 50 a minute. Sinus slowing is due to increased vagal tone and diminished sympathetic tone. It may be induced by carotid sinus massage.

Ætiology—Sinus bradycardia occurs (1) during convalescence from some infectious fevers, especially influenza, diphtheria, typhoid and typhus, (2) in certain toxic conditions such as jaundice, diabetes and anæmia, (3) in hypothyroidism,

(4) occasionally in organic heart disease such as aortic stenosis; (5) as a result of certain drugs, *e.g.* digitalis, opium and its derivatives; (6) in increased intracranial pressure, especially in patient with cerebral tumours; (7) in vaso-vagal fainting-reactions.

Diagnosis.—Sinus bradycardia may be distinguished from the various forms of heart block by clinical correlation of the arterial pulse, the venous pulse and heart sounds (see p. 831). The heart rate is increased by effort, emotion, fever, the nitrites and atropine in sinus bradycardia, but not in heart block. The electrocardiogram is diagnostic.

SINUS ARREST (SINO-AURICULAR BLOCK).—The sinus node may be inhibited by increased vagal tone so that the whole heart is stopped for one or more beats. These dropped beats may occur at irregular or regular intervals. If normal conduction is not soon resumed, nodal or ventricular escape beats occur. As in sinus bradycardia, carotid sinus pressure may induce the condition, and atropine abolishes it. Occasionally a transient dizziness or even syncope may occur.

This condition occurs in normal individuals and should be regarded as an extreme example of sinus bradycardia. It may be caused by digitalis or quinidine poisoning. Treatment is not usually indicated (see Heart Block, p. 832).

SINUS ARRHYTHMIA.—The sinus node sometimes shows phasic activity, which is due to variations in vagal tone. The regular arrhythmia is most often related to respiration and the heart rate increases during inspiration and gradually diminishes during expiration. Phasic arrhythmias are most apparent in the young, in the presence of sinus bradycardia and when digitalis is used.

Diagnosis is usually obvious. An electrocardiogram is confirmatory when there is doubt. This condition should be disregarded. Its significance is in the differential diagnosis from serious arrhythmia.

ECTOPIC BEATS

Synonym.—Extrasystoles, Premature Contraction or Premature Systoles.

Ectopic beats are premature contractions arising as the result of impulse formation at a site other than the sino-auricular node. They may arise in the auricles, auriculo-ventricular node or the ventricles. Most ectopic beats are followed by a diastolic pause which is longer than normal (compensatory pause) because the following sinus impulse falls on refractory tissues. Occasionally the ectopic beat occurs early in the cycle and muscle recovers in time for the next sinus beat to occur without a pause—this is then a true "extrasystole" and is referred to as an *interpolated* beat.

Ectopic beats are the commonest cause of arrhythmia and those of ventricular origin are the commonest variety. They may occur at rare intervals or may be frequent and irregular, or regular. When premature contraction follows each normal contraction, coupling is produced and the pulse shows bigeminy. Ectopic beats may occur in short runs and occasionally an ectopic rhythm may be established. Premature contractions may be very frequent and arise from different foci in the same patient. The prematurity of the contraction results in subnormal ventricular filling so that the stroke volume is smaller than normal. Thus the ectopic pulse wave is smaller and often insufficient to be felt at the wrist, resulting in an intermittent pulse although the ectopic heart sounds will be heard on auscultation. Sometimes the premature contraction is so feeble that closure of the aortic valves is not heard; in this way a group of three sounds (two normal and one ectopic) is heard.

AURICULAR EXTRASYSTOLES.—Here the ectopic focus is in the auricular myocardium and conduction to the ventricle follows a normal pathway thereafter. The compensatory pause is usually short. Occasionally the ectopic auricular sound may be heard preceding the first heart sound.

The electrocardiogram is diagnostic. As might be expected, the P wave is abnormal

and may be superimposed on the T wave of the preceding sinus beat. The premature ventricular complex has a normal or almost normal QRS, occasionally it is absent, the ventricle is refractory and the auricular ectopic stimulus is "blocked".

NODAL EXTRASYSTOLES—Here the ectopic focus is in the auriculo ventricular node and excitation passes in a retrograde fashion over the auricle and normally to the ventricle. The P wave is inverted in leads where it is normally positive and it may occur immediately before, during or immediately after the ectopic QRS complex.

VENTRICULAR ECTOPIC BEATS—The ectopic focus may lie anywhere in the ventricular muscle. The compensatory pause is long because the normal rhythm of the sinus node is not inhibited and the ventricle does not usually respond to the first stimulus after the ectopic beat, normal rhythm is resumed with the arrival of the second normal sinus impulse.

The electrocardiogram shows a premature and bizarre QRS complex often resembling bundle branch block. Right ventricular extrasystoles show a positive main deflection in left ventricular leads whilst left ventricular extrasystoles show the opposite.

Etiology—Ectopic beats occur at any age in either sex, but they are rare in childhood and increase in frequency throughout adult life. They are more common in men than women.

Most patients with premature beats show no evidence of organic heart disease however the diseased heart shows an increased tendency to form ectopic beats. When there is ventricular disease ventricular ectopics are common and when there is auricular disease as in mitral stenosis, auricular ectopics tend to occur and may herald the onset of fibrillation but the relationship is not a close one and all forms of premature contractions occur throughout the range of organic heart disease particularly when the muscle is directly affected.

It is unusual to detect any cause for ectopic beats in patients without gross organic heart disease but mental and physical fatigue increase their occurrence as does excessive use of tea, coffee, tobacco and alcohol. Emotional stress and unusual physical effort are also common provoking factors. Premature contractions are especially apt to occur during rest following physical exertion soon after getting into bed with change of posture and after large meals. They not infrequently occur in association with attacks of migraine and digestive disturbances. Premature contractions may be caused by digitalis and pressor amines and occur frequently during surgical anaesthesia.

Clinical Features—Many individuals are unconscious of ectopic beats even when examination shows gross irregularity. Others experience palpitation a sense of missing a beat a large thumping in the chest or a sensation of the heart turning over, whilst some declare that the heart stops. Occasionally more serious symptoms of faintness and even syncope may appear. The premature beat may be felt at the radial pulse or the pulse may be intermittent. When the ectopic pulse does not reach the wrist, auscultation reveals the sounds of premature contraction.

Diagnosis—In most patients a correct diagnosis can be made by palpation of the pulse and auscultation. The premature beat and following pause may be detected at the wrist. On auscultation the first and second heart sounds of the normal beat are followed in a rapid cadence by one or two sounds of the ectopic beat. When the pulse is interrupted by a long pause partial heart block is excluded by palpating or hearing an ectopic beat at the apex. However the occasionally inaudible or blocked ectopic beat necessitates an electrocardiogram for diagnosis. Sinus arrest may also confuse.

Coupled extrasystoles (pulsus bigeminus) may be confused with pulsus alternans and occasionally with pulsus bisferiens. In pulsus alternans the alternating weak and strong beats are equally spaced and the rhythm is quite regular whereas in coupling the weak beat is clearly premature. In pulsus bisferiens the pulse wave is split and rarely this bifidity may be enough to resemble two close but separate waves. auscultation

tion reveals that a single heart beat is responsible and also reveals the presence of combined aortic stenosis and incompetence which causes a bisferiens pulse.

Frequent extrasystoles, especially if auricular in origin, may produce an extremely irregular pulse which may be difficult to differentiate from auricular fibrillation. Tachycardia induced by effort or drugs tends to diminish the frequency of ectopic beats but in all cases an electrocardiogram is diagnostic.

Prognosis depends on the nature of any associated heart disease.

Treatment.—As previously indicated, most premature beats are asymptomatic. When the arrhythmia is discovered in the course of examination, the patient should not be informed. Patients who are aware of the condition should be reassured firmly and they should be dissuaded from feeling the pulse. Many respond to reassurance and require no other treatment. Where anxiety and the ectopic beats persist, a sedative should be used. Occasionally when there is much anxiety and distress due to frequent extrasystoles, more intensive therapy is indicated. Smoking should be avoided or diminished, sedation with phenobarbitone in doses of gr. $\frac{1}{2}$ to 1 t.d.s. should be given and quinidine sulphate in doses of gr. 1 to 5 three times daily may be tried with good effect. When there is associated heart disease, this should be reviewed and treated.

Nodal rhythm occurs when the auriculo-ventricular node becomes the pacemaker. The auricle is activated by a retrograde spread of the stimulus. The electrocardiogram shows the same changes in each complex as are seen in isolated nodal ectopic beats. This condition occasionally occurs in normal subjects, but it is more often associated with heart disease.

AURICULAR TACHYCARDIA (PAROXYSMAL)

Synonyms.—Auricular Tachycardia, Paroxysmal Tachycardia, Supraventricular Tachycardia.

This is the common form of paroxysmal tachycardia but it should be noted that other tachycardias may occur in paroxysms. In this condition there are repeated attacks of rapid beating. The onset and termination are sudden. The arrhythmia arises at a single ectopic focus which may be high or low in the auricle. The auricular rate is usually between 150 and 220 per min., and mostly there is 1:1 conduction to the ventricle which therefore contracts at the same rapid regular rate. The individual beats are essentially the same as isolated auricular ectopic beats, which may precede or follow the termination of an attack. Paroxysms may last for a few minutes up to a few days. They may recur rarely or with great frequency.

Ætiology.—The ætiology is unknown. As with extrasystoles, patients with normal or diseased hearts may be affected. Paroxysmal tachycardia may occur at any age; it is rare in infancy and increases in middle life, being less common after the sixth decade. Both sexes are equally affected. Paroxysmal tachycardia may occur in any form of heart disease but patients with mitral stenosis, hyperthyroidism and auricular septal defect are more commonly affected. It is not infrequently associated with anomalous auriculo-ventricular conduction (see Wolff-Parkinson-White Syndrome, p. 833).

Most attacks appear spontaneously but in some patients a sudden change of posture, excessive emotion, or physical exertion may provoke an attack. Tea, coffee, alcohol and tobacco may be aggravating factors.

Clinical Features.—The common complaint is of severe palpitation commencing suddenly with little warning. Sometimes a "heavy beat" or "lunge" of the heart signifies an ectopic beat which precedes the main burst of palpitation. Although cessation is equally sudden, this change to normal rhythm is not appreciated so frequently as the sudden onset. The rapid heart beat may affect the whole body with pulsation, some patients will say that the bed appears to shake. Attacks may be

accompanied by sternal discomfort and relative coronary insufficiency may develop producing severe ischaemic pain. A sensation of faintness or giddiness is common and rarely syncope may occur. Many patients experience sensations of great anxiety and extreme exhaustion. There is often much flatulence and abdominal distension, vomiting may occur and this usually terminates the attack. Attacks of migraine are sometimes associated with paroxysmal tachycardia. With very fast rates a shock like condition may appear with coldness of the extremities, perspiration and extreme pallor and faintness. Rarely congestive heart failure may develop especially in patients with pre-existing heart disease in the very young and when paroxysms continue for long periods.

The physical signs are tachycardia (140 to 220) and those of any associated disease. If congestive heart failure develops it rapidly improves with cessation of the attack, which is not infrequently followed by polyuria.

Diagnosis depends mainly on a history of repeated sudden attacks of tachycardia without cause. An electrocardiogram in the attack is diagnostic. Sinus tachycardia is distinguished by its slow onset, slow decline, variable rate and the knowledge of its cause. Carotid sinus pressure causes slight slowing in the sinus rhythm but in auricular tachycardia there is either no effect or a sudden return to normal rhythm.

Auricular flutter causes a similar fast heart rate and should be distinguished (see p 825). Clinical recognition is sometimes possible if two auricular venous pulse waves to each ventricular systole can be detected. Auricular flutter may continue for weeks or months whereas paroxysmal auricular tachycardia lasts for minutes or hours. Differentiation from the electrocardiogram may also be difficult. There is 1:1 conduction in auricular tachycardia but the alternate P waves in 2:1 auricular flutter may be buried in the QRS complex and therefore difficult to detect. When the pulse is irregular and fast, auricular fibrillation is the usual cause (see p 826). Paroxysmal ventricular tachycardia is rare and associated with serious disease of heart muscle (for diagnosis see p 828).

Prognosis—The outlook for individual attacks is good, cessation occurs spontaneously after a short period. However, when there is organic heart disease or when attacks are resistant to treatment and the tachycardia persists for a long time, congestive cardiac failure may develop. Persistent attacks occasionally cause coronary insufficiency and muscle damage. In infancy long attacks may be lethal from heart failure. From the long term point of view, prognosis is very good for the vast majority of patients. Attacks may be infrequent and they rarely interfere with work and normal employment. They may cease as mysteriously as they started and the physician should invariably give an encouraging prognosis.

Treatment—In most patients with paroxysmal tachycardia there is anxiety and attacks are often more frequent during phases of heightened emotional tension. Confident reassurance is thus essential and it should be stressed that the heart is healthy and that sudden death is no more likely than in other people. In rare cases where the attacks are associated with serious organic heart disease and cardiac failure is present or a possibility, digitalis should be given indefinitely.

Many patients learn a simple method of terminating the attack such as breath holding, drinking iced water or self induced vomiting. Carotid sinus massage is however, the most effective, with the neck extended in a reclining posture the carotid sinus region is firmly massaged on one side only and this procedure may be repeated on the opposite side. It should not be carried out in elderly, arteriosclerotic subjects. In severe prolonged attacks it is advisable for the patient to lie down and gr 3 of quinidine together with gr 1 of phenobarbitone, should be given. Most attacks then cease within 8 hours, whether this is spontaneous or due to quinidine or sedation is uncertain. Intravenous digoxin (1 mg) (or Lanatoside C) should be tried and is usually effective in attacks which continue after quinidine has been used without success. Cholinergic drugs have unpleasant side effects and are not advised unless

sedation, quinidine and digitalis have failed. Prostigmine is given intravenously or intramuscularly in doses of 1 mg. Acetyl β methylcholine chloride (Mechoyl) may be given subcutaneously in doses of 10 to 20 mg. as it acts in less than 5 minutes, and often the gut and bladder are more dramatically affected than the arrhythmia. Hypotension is a serious toxic effect. Cholinergic action may be abolished by intravenous atropine (1 mg.) if any of the side effects is serious. It is emphasised that at least 95 per cent. of attacks may be terminated by less drastic methods. Patients having only occasional attacks need advice about the individual attack, but no long-term treatment other than reassurance and perhaps an occasional sedative. When attacks are frequent, gr. 3 to 5 of quinidine t.d.s., should be given for a trial period of 2 to 3 months and if the frequency of attacks is reduced and the drug is well tolerated, it should be continued indefinitely.

Paroxysmal tachycardia in infancy is serious and may lead to congestive heart failure, digitalis is indicated and is almost always effective.

AURICULAR FLUTTER

Auricular flutter is a condition of rapid auricular pulsation of 180 to 360 beats per minute. The onset is sudden. In the majority of cases there is partial auriculo-ventricular block varying from 2:1 to 5:1, the former being more common. Ventricular rates are usually from 130 to 180 per minute. Investigations by Lewis suggested that flutter was due to a continuous circus movement of excitation in the auricular myocardium, more recent work indicates that there is rapid stimulus formation at a single focus from which waves of activity spread through the auricles in all directions.

The rate of stimulus formation in this condition is faster than in the auricular tachycardias and slower than in auricular fibrillation, but in each condition ectopic stimulus formation appears to be the fundamental disorder. Investigations by Prinzmetal show that the ectopic focus tends to be at the caudal end of the auricle in flutter and at the cephalic end in auricular tachycardia. Auricular flutter is much less common than either auricular tachycardia or auricular fibrillation. Paroxysms of flutter usually last much longer than those of paroxysmal tachycardia (auricular) and conversion to auricular fibrillation occurs readily, there is much overlap between the two conditions.

Etiology—Auricular flutter is almost always associated with either ischaemic or rheumatic heart disease. Men are most commonly affected. It may be responsible for tachycardia in infancy but otherwise is unusual under 40 years of age and most common after 60.

Clinical Features—Auricular flutter may cause the same symptoms as paroxysmal tachycardia (see p. 823). Ischaemic heart pain may occur and a persistent attack of auricular flutter may precipitate congestive cardiac failure.

Heart rate is usually rapid and regular, but there may be sudden changes in rate due to a variable degree of auriculo-ventricular block. Exercise and emotional change leave the rate unaltered, but carotid sinus or eyeball pressure may result in a sudden rate change. When the degree of block is high (4:1) the ventricular rate may be normal. The loudness of the first heart sound may be variable when there is a varying degree of block. Sometimes the auricular waves ('a' waves) may be seen in the neck, and their regular relationship to the less frequent ventricular pulse detected.

The electrocardiogram—P waves are regular at rates from 200 to 350 per minute. They are most readily seen in leads II and III or right sided precordial leads, especially CR1. The P waves often show a continuous undulating pattern without an iso electric interval, this appearance is due to the auricular T waves. P waves are also abnormal in form, depending on the site of ectopic impulse formation. None of these criteria is absolute. The level of auriculo-ventricular block determines the

frequency of the QRS complex. When there is 1:1 conduction P waves may not be distinguished and the appearance may be confused with ventricular tachycardia. Vagal stimulation leaves the P waves unchanged whilst the QRS complexes may become irregular or recur at a regular slower rate.

Prognosis—Prognosis depends largely on the nature of any underlying heart disease. Prolonged attacks may precipitate heart failure when there is pre-existing heart disease but when the heart is otherwise normal auricular flutter may be tolerated well for years. Attacks of auricular flutter tend to recur, but they are extremely variable in duration and in frequency of recurrence.

Treatment—In all cases underlying heart disease should be reviewed and congestive heart failure treated by the usual methods. In the rare cases where natural heart block keeps the heart rate normal there are no symptoms and no treatment is indicated but in others digitalis is the drug of choice. Digitalis is given to slow the ventricular rate and to produce auricular fibrillation which is more easily controlled than auricular flutter and more readily converted into normal rhythm.

Digitalis folia (or other preparations of the physician's choice see p. 814) should be given in doses of gr. 3 t.d.s., on the first day gr. 2 t.d.s. and gr. 1 t.d.s. on the second and third days with a maintenance dose of gr. 1 b.d. Auricular fibrillation frequently follows this régime. Many patients however, remain in auricular flutter and in these the ventricular rate should be controlled by digitalis. Little is gained by using other anti-arrhythmic drugs as in most cases underlying organic heart disease prevents the continuation of normal rhythm. Patients in whom auricular fibrillation has developed should be maintained on digitalis but in some where there is no serious organic heart disease quinidine should be used (see treatment of auricular fibrillation p. 828).

AURICULAR FIBRILLATION

Auricular fibrillation is the most common and one of the more serious of the persistent arrhythmias. Integrated auricular contraction disappears and is replaced by rapid irregular fibrillary twitching of the auricular muscle and there is irregular rapid ventricular contraction. Paroxysms may occur but mostly auricular fibrillation becomes a permanent condition.

As in the case of auricular flutter Lewis came to the conclusion that auricular fibrillation was due to a single excitation wave travelling around a main circus path and giving rise to lateral daughter waves. This circus theory has been generally accepted but recent investigations particularly by Prinzmetal and his associates using the high speed cinematograph and cathode ray oscillograms have shown no evidence of circus movement centrifugal waves or daughter waves. This recent work shows that auricular fibrillation is characterised by a chaotic disturbance of auricular muscle found only in this condition. There are asynchronous pulsations of minute segments of muscle larger movements of larger areas of muscle and all intermediate varieties which may occur simultaneously or separately. It appears that the arrhythmia is initiated from a single ectopic focus but the larger movements arise from diverse foci and they pass over the auricle from 400 to 600 times a minute. These larger waves may pass in any direction during a given bout of fibrillation and they vary greatly in intensity of contraction.

With auricular fibrillation there is usually a degree of auriculo-ventricular block. Stimulation of the ventricle is irregular and the rate is usually between 100 and 180 beats per minute. Some patients especially when there is long standing mitral stenosis, show a high degree of A-V block and the rate may be normal. Digitalis is however mostly responsible for slow ventricular rates accompanying auricular fibrillation.

Auricular fibrillation diminishes the efficiency of the heart. There is good evidence

to show that cardiac output rises when normal rhythm is restored; however, from the clinical point of view the circulation may show little evidence of inefficiency if the ventricular rate is controlled by digitalis.

The electrocardiogram.—The characteristic feature of the electrocardiogram is the disappearance of P waves and their replacement by irregular waves of varying size called "f" waves, and usually best seen in right chest leads. The ventricular complexes are irregular and vary slightly in contour, but have the same general form as those found when the patient is in normal rhythm. If they appear to be regular, measurement of successive RR intervals reveals the underlying irregularity.

Ætiology.—Auricular fibrillation is mostly associated with organic heart disease. However, in 7 to 10 per cent. of patients the heart muscle and valves are apparently normal; these patients have a good prognosis.

Any type of organic heart disease may be associated with auricular fibrillation, but mitral stenosis, ischæmic heart disease and hyperthyroidism accounts for most cases. Auricular fibrillation occurs in the course of most patients with mitral stenosis, and the establishment of permanent arrhythmia may be preceded by frequent auricular ectopic beats or paroxysms of auricular fibrillation. Patients with great enlargement from mitral stenosis always have auricular fibrillation, but heart failure commonly occurs whilst there is still normal rhythm.

Auricular fibrillation may be continuous or paroxysmal in hyperthyroidism and its frequency increases with advancing years. Auricular fibrillation is common in chronic ischæmic heart disease and may be due to occlusion of the artery to the sinus node. Although many patients with hypertension develop heart failure with normal rhythm, auricular fibrillation sometimes occurs, particularly when coronary artery disease is also present. It is rare in malignant hypertension. Transient attacks of auricular fibrillation are common in patients with recent cardiac infarction. Constrictive pericarditis is associated with auricular fibrillation in at least one-third of the cases, but in other forms of pericarditis, arrhythmia is rare. Auricular fibrillation is sometimes associated with non-cardiac disease, especially in carcinoma of the bronchus and other neoplasms in the chest and mediastinum when there is involvement of cardiac nerves or direct invasion of the pericardium and heart. It occasionally occurs in apparently normal hearts. Sudden physical or mental shock may precipitate the arrhythmia in some patients whilst in others there is no apparent cause. Auricular fibrillation may occur at any age and in either sex.

Clinical Features.—Some patients are unaware of any irregular heart action but many experience palpitation. Dizziness, syncope and cardiac pain sometimes accompany an attack of auricular fibrillation. Heart failure may develop, symptoms are then determined by its severity, and the nature of the underlying heart disease.

Systemic and pulmonary emboli are common complications of auricular fibrillation and are especially likely to occur if the arrhythmia changes to sinus rhythm.

Diagnosis.—Auricular fibrillation is recognised by total irregularity of the pulse in rhythm and volume. Before treatment is given there is mostly tachycardia and some of the weaker beats may not be appreciated at the wrist so that a pulse deficit is usual. Frequent irregular ectopic beats may resemble auricular fibrillation, but in most cases the basic regularity of sinus rhythm can be recognised and exercise tends to produce a more regular pulse. A slow ventricular rate in auricular fibrillation from natural heart block or digitalis therapy may result in an almost regular pulse. When there is doubt an electrocardiogram is confirmatory.

Treatment.—The management of patients with auricular fibrillation depends to some extent on its cause, and in all cases the possibility of thyrotoxicosis should be borne in mind and excluded as an ætiological factor.

All cases with tachycardia, or any evidence of congestive cardiac failure, require digitalis which should be used in routine doses of the preparation of choice. Digitalis

folia is satisfactory and gr. 3 t.d.s. on the first day, followed by gr. 2 t.d.s., and gr. 1 t.d.s. on the second and third days, followed by a maintenance dose of gr. 1 b.d. which is adequate for most cases. Occasionally more rapid digitalisation is necessary, when intravenous digoxin or Lanatoside C may be used (see p. 814).

Conversion of auricular fibrillation to normal rhythm must be considered in all cases where auricular fibrillation is of functional origin, and where there is no evidence of serious organic heart disease. Conversion should also be attempted in successfully treated hyperthyroidism if spontaneous reversion has not taken place, it should also be attempted in cases of mitral stenosis after successful mitral valvotomy. Quinidine is the anti-arrhythmic drug of choice: it should be combined with digitals in all cases where there is underlying heart disease and the possibility of heart failure. It is traditional to give a test dose of quinidine (gr. 2), but there is no evidence that this has any value. There are various recommended schedules for the oral administration of quinidine, the following one is satisfactory: gr. 5 four-hourly on the first day, gr. 5 two-hourly on the second day and repeated on the third day. The course is stopped when conversion to normal rhythm occurs or at the end of the third day, or if serious toxic effects occur. Toxicity is shown by vomiting, diarrhoea, hypotension and even syncope—the drug should be withdrawn if any one of these appears. Quinidine is an abortifacient drug and should not be used during pregnancy. If conversion to normal rhythm has occurred as a result of quinidine therapy a maintenance dose of gr. 5 t.d.s. should be continued for a few weeks.

VENTRICULAR TACHYCARDIA

Ventricular tachycardia is a condition of rapid regular rhythm which is initiated from a focus in the ventricle. It may be paroxysmal or continuous and is almost invariably associated with serious organic heart disease affecting left ventricular muscle. Acute cardiac infarction is the cause in 75 per cent. of cases of ventricular tachycardia. Digitalis intoxication may be a precipitating or aggravating factor. Rarely there is no evidence of organic heart disease.

Symptoms are those of paroxysmal tachycardia; there may be little subjective disturbance or symptoms are submerged in those of cardiac infarction or heart failure. Ventricular tachycardia may be responsible for relatively sudden and rapid deterioration in the course of cardiac infarction. Examination shows a regular rapid heart rate between 150 and 300 per minute. Hypotension, peripheral constriction and sweating may indicate the development of shock.

The electrocardiogram shows abnormal QRS complexes which are widened and may resemble those of ventricular ectopic beats. There is slight irregularity of rhythm. P waves are rarely recognisable but during episodes of regular rhythm they are normal, whereas the QRS complexes usually show evidence of serious myocardial disease.

Diagnosis.—Paroxysms of tachycardia occurring during the course of serious organic heart disease suggest a ventricular origin, particularly in cardiac infarction, hypertension or aortic valve disease. The diagnosis is confirmed by the electrocardiogram. In supraventricular tachycardia the QRS complexes are frequently normal and regular, whereas in ventricular tachycardia the QRS is obviously abnormal and not quite regular. The electrocardiogram of supraventricular tachycardia with functional bundle branch block may not be distinguishable from that of ventricular tachycardia.

Treatment.—Quinidine is the anti-arrhythmic drug of choice. It should be given orally in the first instance as described for auricular fibrillation (see above). If oral quinidine is not effective or if deterioration in the patient's condition demands more urgent treatment intravenous procaine amide (5 to 10 ml. of 1 or 2 per cent. solution), or magnesium sulphate (20 ml. of 20 per cent. solution), or quinidien

lactate (gr 10 of quinidine in 50 ml of 5 per cent glucose at a rate not exceeding 2 ml per minute) should be given slowly and controlled by serial electrocardiograms where possible. The injection should be stopped if normal rhythm develops, or if serious toxic symptoms develop, oral quinidine should then be given in doses of gr 5 tds for a few weeks.

Although the above measures are not without danger of serious toxic effects the gravity of ventricular tachycardia in cardiac infarction demands effective and urgent treatment.

DISORDERS OF CONDUCTION

Conduction of the excitatory impulse may be delayed or interrupted at any point during its passage from the sino auricular node over the rest of the heart. The site and degree of delay may be determined and forms a basis of classification as follows.

- (1) Sino auricular block
- (2) Auriculo ventricular block (usually known as heart block and including prolonged PR interval, partial and complete heart block)
- (3) Bundle branch block and intraventricular block

SINO-AURICULAR BLOCK

Sino auricular block is a relatively rare condition in which the whole heart fails to beat due to an impulse from the sino auricular node not being generated, or possibly because auricular response to the stimulus is blocked. This condition is indistinguishable from sinus arrest (see p 821).

AURICULO VENTRICULAR BLOCK (HEART BLOCK)

In auriculo ventricular block there is defective conduction in the auriculo ventricular node or the bundle of His or both. The condition may be transient, paroxysmal or permanent. There are three grades: (i) Delayed conduction of the impulse from auricle to ventricle, resulting in a prolongation of the PR interval (u) Partial heart block with dropped beats due to intermittent failure of auriculo ventricular conduction (iii) Complete heart block when there is complete auriculo ventricular dissociation.

Some authors group the first and second grades as partial or incomplete heart block, while other writers divide partial heart block into cases where there are irregular dropped beats and those where the conduction defect is regular.

(i) **PROLONGED PR INTERVAL (FIRST DEGREE HEART BLOCK)**—When impulses are delayed in passage through the auriculo ventricular node and bundle there is a prolongation of the PR interval on the electrocardiogram (normal is 0.12 to 0.22 sec). A prolonged PR interval may be transient, a stage in the development of more severe block, or permanent and non progressive. The diagnosis is essentially electrocardiographic but the delay between auricular and ventricular events may be detected occasionally by clinical examination. Abnormal delay between jugular venous "a" waves and c' waves or between auricular components and ventricular components of the first heart sound may be detected. As the PR interval is prolonged the first heart sound becomes softer. In mitral stenosis there may be a gap between the auricular systolic murmur and the first heart sound.

Ætiology—First degree heart block occurs in all conditions which produce complete heart block (see p 830). It commonly occurs in the course of carditis, especially in rheumatic fever where a prolonged PR interval indicates the presence of active carditis. A prolonged PR interval may be a permanent result of scar formation.

(ii) **PARTIAL HEART BLOCK**.—When the cardiac impulse fails to reach the ventricles,

through intermittent failure of auriculo ventricular conduction so that dropped beats occur, the condition is spoken of as partial or second degree heart block. The dropped beats may be occasional, irregular or frequent and regular.

Wenckebach (1899) described a form in which the PR interval becomes progressively longer after each dropped beat until conduction fails again. In other cases the ratio between auricular and ventricular beats may be steady and regular but each second, third or even fourth ventricular beat may fail, producing 2 1, 3 1 and 4 1 ratios, the pulse may then appear to be grouped in runs of twos or threes. Ventricular rate depends on the auricular rate and the degree of block, thus at normal auricular rates and 2 1 block the pulse rate is slow (34 to 40 beats per minute), whereas with an auricular tachycardia and partial heart block the pulse may be rapid. Inspection of the jugular venous pulse may show an "a" wave corresponding to the dropped ventricular beats and an auricular sound may be heard at the same time, but an electrocardiogram is necessary for confirmation.

The electrocardiogram shows the frequency of absent QRS complexes compared with the frequency of regular P waves. Lead II or a right sided chest lead should be examined when P waves are not clearly shown in other leads. A progressive lengthening of the PR interval followed by a dropped beat is the Wenckebach phenomenon.

Ætiology (see Complete Heart Block)

Prognosis—Partial heart block nearly always indicates heart disease and implies damage to the myocardium. The condition may be transitional to complete heart block. Prognosis depends on the nature of the underlying heart condition.

Treatment depends on the nature of associated heart disease.

(iii) **COMPLETE HEART BLOCK**—In complete auriculo-ventricular block the cardiac impulse fails to reach the ventricles which continue to beat in response to a focus which is situated in the conducting tissues of the ventricular septum. The inherent rhythmicity of ventricular foci is slow and slightly irregular, being almost totally uninfluenced by external stimuli so that fever and effort leave the pulse rate unaltered. There is some evidence that vagal activity has a slight effect. The condition is spoken of as complete auriculo ventricular dissociation, and the ventricular beating as an idioventricular rhythm. The slow rate results in increased ventricular filling, the stroke volume is large and tends to maintain a near normal cardiac output at rest.

Ætiology—There are many causes of delay in the conducting system, the higher grades of auriculo ventricular block are usually associated with chronic serious heart disease, causing anatomical lesions of the conducting system, whereas in the lesser grades of block, which may be transient, the causative factors may be self limiting, reversible and of a functional nature. The frequency of serious heart block increases with age and it is more common in men than in women. The more important causes are *Ischemic heart disease*. Chronic coronary athero-sclerosis leading to fibrosis of the A-V node and bundle is the commonest cause of complete heart block, which is then a permanent condition. Involvement of junctional tissues is usually part of widespread myocardial fibrosis but occasionally the special artery to the bundle which is a branch of the right coronary artery, is occluded and the lesion is more limited. Acute cardiac infarction sometimes causes transient heart block. *Calcific aortic stenosis* may be associated with various degrees of heart block. Calcification and fibrosis extends into the region of the bundle, associated coronary insufficiency is another factor in these cases. Rarely calcification may extend into the bundle from the mitral annulus in chronic mitral valve disease. *Rheumatic carditis* commonly causes first degree heart block, and less frequently severer grades of block. *Diphtheritic carditis* may cause any degree of conduction delay, complete block is more usual and indicates extensive and usually fatal myocarditis. *Syphilis* occasionally causes heart block, probably most cases are due to associated coronary insufficiency from

coronary ostial stenosis, or coronary athero-sclerosis; gummatous infiltration is a rare cause. Infiltration of the node and bundle by neoplasm occasionally produces heart block. Diffuse changes in the myocardium occur in Friedrich's disease and myotonia atrophica, and the bundle of His may be involved, causing an increase of the PR interval and even complete heart block. *Digitalis* is perhaps the commonest cause of the lesser degrees of heart block. The effect is due to vagal stimulation and a direct inhibition of the conducting tissues. Quinidine rarely causes conduction delay. *Congenital heart disease* may be associated with the various grades of heart block. Complete heart block is uncommon but occurs in some cases of ventricular septal defect, and occasionally where the septum is normal. It is very rare in cyanotic congenital heart disease. The ventricular rates tend to be considerably higher than in cases of acquired heart block.

Clinical Features.—The lesser grades of heart block do not usually produce symptoms. The dropped beats of partial heart block may produce unpleasant sensations in the chest; the long pause or the thud of the next beat may be felt and faintness may occur; however, it is with complete block that serious symptoms generally occur. Complete auriculo-ventricular dissociation is mostly associated with a slow heart rate, usually from 30 to 40 per minute. At this rate symptoms may be completely absent but with slower rates faintness is common. Attacks of sudden syncope (Stokes-Adams syndrome) occur in nearly 50 per cent. of cases.

STOKES-ADAMS SYNDROME.—This condition is characterised by sudden attacks of loss of consciousness associated with extreme bradycardia or periods of ventricular asystole. It seems that depression of the idioventricular focus, resulting in very slow ventricular rates is mostly responsible (10 to 20 per minute). The auricle continues to beat at a normal rate whilst the ventricle is inactive.

Loss of consciousness is sudden and unaccompanied by any aura; attacks may last for a few seconds to 1 minute or more; recovery is unlikely after 2 minutes. As asystole continues extreme pallor develops and after some 10 to 12 seconds, movements commence and convulsions may follow. Breathing becomes stertorous and may be of the Cheyne-Stokes variety at the end of an attack. Ventricular fibrillation may supervene. When the ventricular beat is resumed consciousness returns, usually without any period of confusion, and flushing of the face is common. Bed patients have been observed in the course of conversation which has been resumed normally immediately after the syncope.

Attacks may occur at infrequent intervals or in rapid succession. They are particularly likely to occur at an early stage when complete heart block develops from partial heart block. It appears that the idioventricular rhythm becomes more stable when complete heart block is permanent. Rarely complete heart block causing Stokes-Adams attacks may be paroxysmal so that between the attacks there is sinus rhythm. Lesser grades of the syncopal reaction such as giddiness and faintness may occur before and between attacks of complete unconsciousness.

ever, the size and shape of the heart is essentially determined by the underlying pathology.

The electrocardiogram.—P waves are regular or show slight variation and occur at a normal rate and are of normal form. The QRS complex occurs at a slow rate though usually at regular intervals; however, the PR intervals are totally irregular because there is no relationship between the auricular and ventricular complexes. The QRS complex is usually abnormal, being widened and similar to that seen in bundle branch block and ectopic ventricular beats.

Diagnosis.—The diagnosis of all forms of heart block must be confirmed by the electrocardiogram. A prolonged PR interval is not usually diagnosed by clinical methods. Second degree heart block may be diagnosed if attention is paid to ventricular activity as shown by the pulse, apex beat and the first heart sound, and to auricular activity by observing "a" waves in the venous pulse. It should be remembered that sinus irregularity, sinus bradycardia and ectopic beats may be confused with the dropped beats of heart block when attention is only given to the wrist pulse. Although most cases with a ventricular rate of 36 or under are due to complete heart block, a 2:1 partial heart block may occasionally cause difficulty when the auricular rate is normal.

Congenital heart block should be diagnosed only when a slow pulse has been found at an early stage and when there is other evidence of congenital heart disease.

Stokes-Adams attacks normally provide little difficulty in diagnosis when the presence of heart block is known. The suddenness of onset, absence of incontinence and absence of confusion afterwards help to differentiate from epilepsy. When heart block is paroxysmal, diagnosis is difficult between attacks and confirmation of the heart rate at the time of the attack is necessary.

Prognosis.—The prognosis depends mainly on the nature of associated heart disease and severity of the conduction defect. Thus first degree heart block is common in rheumatic carditis and the outlook depends on other factors. Complete heart block in diphtheria, on the other hand, indicates very severe carditis which is usually fatal.

In complete heart block due to slowly progressive ischæmic fibrosis or calcification, a life of moderately reduced activity may be pursued for many years provided syncopal attacks are not present. When Stokes-Adams attacks are frequent the outlook is poor, and apart from the risk of a fatal termination during an attack, death may occur with the usual clinical picture of congestive heart failure. Transient block in acute cardiac infarction does not materially influence prognosis when compared with other factors such as shock and congestive heart failure. The progress of patients with congenital heart block depends almost entirely on the nature of the associated lesion.

BUNDLE BRANCH BLOCK

Activation of both ventricles occurs simultaneously in the normal heart. When there is delayed conduction of the impulse to one ventricle asynchronous contraction results. Unilateral delay may occur in the left or right branch of the bundle of His due to disease in the ventricular septum. In some cases there is no demonstrable disease of the septum and the delay appears to be of a functional nature. There are no symptoms or significant hæmodynamic effects of this asynchronous contraction, and bundle branch block should not be considered apart from the condition of the heart with which it is associated. Although bundle branch block is essentially recognised by the electrocardiogram, its presence may be inferred by clinical recognition of ventricular asynchrony.

The normal second heart sound contains the almost simultaneous sounds produced by the closure of aortic and pulmonary semilunar valves. Inspiration accentuates the normal slight delay of pulmonary valve closure. When there is bundle branch block the asynchrony of ventricular systole is shown by an increased time interval between these two components of the second heart sound so that wide "splitting" results. This sign is most obvious in cases of right bundle branch block.

The electrocardiogram (see also p. 801).—Experimental work and clinical research has established clearly the cardiographic patterns associated with left and right bundle branch block. The P wave and PR interval are normal, but the QRS complexes are prolonged to 0.12 sec. or more due to the delayed activity of one ventricle. The diagnosis of left or right bundle branch block is best made from the precordial leads.

In left bundle branch block the normal O wave is absent from left-sided chest leads and is replaced by a small R wave, which is followed by a second R wave due to late excitation of the left ventricle. The complex tends to resemble an M. The initial R wave of right-sided chest leads is normal but there is a late S wave reflecting the delayed activity of the left ventricle. T waves are usually inverted in left precordial leads.

In right bundle branch block right-sided chest leads show a delayed secondary R wave after the small normal initial R wave producing a characteristic RSR' complex. Left-sided chest leads show a normal left-sided qR wave, followed by a delayed S wave which is a reflection of the delayed right ventricular activity. T waves are frequently inverted in the leads showing an RSR' pattern.

Ætiology.—Left bundle branch block tends to occur in conditions producing left ventricular hypertrophy and left ventricular disease so that it is not uncommon in hypertensive heart disease, ischemia and aortic valve disease. Cardiac infarction may produce right or left bundle branch block, which may be transient or permanent.

Right bundle branch block occurs in conditions particularly affecting the right heart. It occurs in some cases of mitral stenosis, chronic pulmonary heart disease and in 90 per cent. of patients with auricular septal defects. Massive pulmonary embolism commonly produces right bundle branch block. Bundle branch block may occur as a functional phenomenon in association with paroxysmal tachycardia. Right bundle branch block occurs in a few healthy individuals but left bundle branch block is always associated with heart disease.

Clinical Features.—Apart from the clinical recognition of asynchronous ventricular contraction described above, the clinical picture is determined by associated heart disease.

Prognosis and Treatment likewise depend entirely on associated heart disease.

WOLFF-PARKINSON-WHITE SYNDROME.—Although there is no conduction delay in this condition it is conventionally described with bundle branch block. The diagnosis is essentially by electrocardiogram. The PR interval is short (0.1 sec. or

less) and is followed by a QRS complex resembling bundle branch block. The short PR interval is compensated by the prolongation of the QRS complex so that the time between the P wave and the end of the QRS is normal. It appears, therefore, that there is premature ventricular excitation. This premature excitation wave probably travels by an anomalous pathway from auricle to ventricle. Anomalous bundles of tissue have been demonstrated occasionally by histological examination.

The condition may be permanent, transient or paroxysmal. Normal QRS complexes may alternate with pre excitation ones. The heart is mostly normal but paroxysmal tachycardia occurs in 50 per cent of cases.

ISCHÆMIC HEART DISEASE

Ischæmic heart disease includes all conditions which are due to a failure of the coronary circulation to meet the demands of cardiac muscle. As a rule the coronary arteries are diseased so that the term is almost synonymous with coronary heart disease, and in most cases atheroma is the cause. Angina pectoris is a clinical syndrome and is restricted to the diagnosis of paroxysmal cardiac pain due to coronary disease. Cardiac infarction indicates a clinical syndrome but also refers to pathology because it is essentially associated with necrosis of heart muscle. Coronary thrombosis refers to pathology and is almost synonymous with cardiac infarction but occasionally either condition occurs without the other. Acute coronary insufficiency refers to an acute severe functional disturbance and may be recognised as a clinical syndrome having some of the features of angina pectoris and some of cardiac infarction. Such terms as coronary infarction, cardiac thrombosis, angina innoccens, pseudoangina and angina minor should never be used.

The clinical picture largely depends on the rate of development and extent of myocardial ischæmia. The main syndromes, angina pectoris, cardiac infarction and coronary insufficiency may occur in any sequence in combination, or as isolated events. The slow development of ischæmic heart disease may rarely lead to impaired function and heart failure without cardiac pain. The disease should be regarded as a continuous process with cardiac infarction as the outstanding event responsible for deterioration in circulatory efficiency.

Ætiology—All forms of ischæmic heart disease are manifestations of one disease process the essentials of which are a discrepancy between the supply of oxygen and the requirements of heart muscle. Occlusive disease of the coronary arteries, usually atheroma, is the cause but ischæmia may be relatively increased by the abnormal requirements of muscle hypertrophy or greatly increased external work.

The cause of coronary atheroma is unknown. There has been a great increase in the incidence of all manifestations of ischæmic heart disease during this century in modern Western states. This increase is real and cannot be accounted for by improved methods of diagnosis or a changing age distribution of the population. Ischæmic heart disease is the commonest single cause of death and probably accounts for 50 per cent of all cardiac deaths.

Males are much more commonly affected than females, when hypertension, diabetes and other endocrine disorders are excluded, coronary disease is rare in women below 60 years of age. This sex difference must have an important association with the cause. Coronary artery disease is more frequent in the higher age groups but it is not uncommon under the age of 40 in men and conversely many aged people show little evidence of atheroma. Indeed the absence of atheroma is a prerequisite of attaining great age. It is doubtful whether coronary atheroma leading to ischæmic heart disease should be regarded in any way as a part of the normal ageing process. Most authorities agree that hereditary factors are important in the pathogenesis of coronary disease. There is a relatively high incidence of coronary disease, hyper

tension and degenerative vascular affections in the close relatives of patients with coronary disease, however, the relationship is by no means a close one and in general a common disease in the community is more likely to be due to environmental factors than genetic ones.

There is considerable evidence that abnormal lipid metabolism is a factor in the development of atherosclerosis (see p 919). There is a higher incidence of atheroma in modern states where diets contain much more animal fat than those of primitive peoples, in whom atheroma is almost unknown. It is obvious that many other factors may be operative, and it has not yet been shown that decreasing the dietary intake of fats and cholesterol influences the severity or incidence of ischæmic heart disease. Further evidence for the metabolic theory comes from the laboratory, where atheroma may be produced in rabbits and chicks by feeding large amounts of animal fats and cholesterol, the conditions are not comparable with those in man and the lesions produced, though closely resembling human atheroma, are not identical. Many patients with coronary disease show rather high levels of blood cholesterol and certain other lipid substances. The high incidence of coronary atheroma in diseases associated with high blood levels of cholesterol, *e.g.* diabetes, myxœdema and familial hypercholesterolaemia, strongly suggests that abnormal lipid metabolism is an ætiological factor in these conditions. Further evidence comes from the histopathology of the lesions in human atheroma, where deposits of cholesterol in the intima are invariably found. Excess cholesterol esters are thought to adhere to the intimal wall and to be deposited in it by macrophages, a connective tissue reaction is then provoked, with resultant scar formation.

When diseases such as coronary occlusion and peptic ulceration are not only common but especially prevalent in particular communities and groups within the community, it is probable that environmental factors play a considerable part in their ætiology. There appears to have been a fundamental change in the mode of life in civilised communities during the last half century. Coronary disease has shown a continuous tendency to increase during this period, it is possible that new conditions of stress especially affecting certain groups are an important ætiological factor. Those whose occupations are largely concerned with mental work, carrying responsibility, and whose lives are more individualised than the manual worker, are thought to be the special subjects of modern stress, they are the professional men, the managerial and executive classes who are often in tense competition with one another, and whose aims are set high yet are largely unattainable. These groups have numerically increased during the past century and coronary disease has selectively increased within these classes. Improved diagnosis, increased longevity and the diminution of previously prevalent infectious diseases do not account for the present status of coronary disease, and its cause must account for an increasing incidence and the great prevalence amongst middle aged men. There is some evidence to show that diminished physical activity predisposes to coronary disease or conversely that coronary disease is less likely to occur in those whose occupation necessitates a vigorous outdoor life.

Less common causes of ischæmic heart disease are syphilitic coronary ostial stenosis (see p 859), coronary embolism, periarthritis nodosa (see p 931), thromboangitis obliterans (see p 921) and congenital abnormalities of the coronary arteries. Trauma to the præcordium is a rare cause of ischæmic heart disease, blunt, non-penetrating blows have been held responsible for coronary occlusion and infarction but it is difficult to exclude pre-existing coronary atheroma even in young subjects (see p 834). Penetrating injuries which damage the coronary circulation largely produce their effects through the development of hæmopericardium.

Pathology—*The coronary arteries*—All degrees of atheroma are found in the coronary arteries from small, infrequent, yellowish plaques on the intima to extensive thickening of the whole vessel with irregular large plaques encroaching upon the

lumen Macroscopic calcification and ulceration of atheromatous plaques is common and the whole vessel may become a "pipe stem". Localised complete occlusion of the vessel may be due to large contiguous plaques of atheroma, fresh thrombosis on an ulcerated plaque, or more rarely to hæmorrhage in the intima. The morphology of the coronary circulation may be demonstrated by radiography of the heart after the injection of opaque media into the coronary arteries. Complete occlusion occurs in any branch but the commonest sites are in vessels supplying the left ventricle at a point to 2 to 3 cm from their origin. The tendency to form collateral channels in the vicinity of an occlusion is well shown by this method and it appears to be a common finding. In long standing cases the normal homogeneous vascular pattern is lost and replaced by ischæmic areas with a fine lace-work of vessels between. The major arteries show gross irregularities and narrowing of the lumen.

Microscopical changes are principally found in the intima. The smallest lesions show large lipid-containing mononuclear cells, whilst in larger lesions and presumably older ones, masses of cholesterol are found outside the cells. The adjacent intima and the margins of atheromatous plaques are supplied by numerous capillaries but the larger lesions appear to undergo central necrosis where a mass of lipid and cells may form an atheromatous abscess which tends to break down with resulting ulceration. The elastic and muscle coats may be completely absent and replaced by fibrosis. Microscopic sections through an area of thrombotic occlusion sometimes show layers of thrombus in varying states of organisation, with a central fresh thrombus responsible for the final obstruction.

The myocardium—All degrees of damage to the left ventricular myocardium are found in ischæmic heart disease. The right ventricle and auricles are rarely affected. When sudden death has occurred in the course of angina pectoris, the heart size and weight may be normal and the myocardium may show little macroscopic evidence of disease whilst microscopic examination may show only an occasional patch of fibrosis. In other cases more widespread fibrosis is found either in frequent scattered patches or widely diffused throughout the muscle mass. This type of fibrosis probably represents a slow process of muscle death and replacement.

In recent cardiac infarction the heart may be of normal size, but it is usually dilated when there has been heart failure. A sero fibrinous or sero sanguinous pericarditis is common and occurs when the epicardium is involved. The pericardial sac is full of blood when cardiac rupture has occurred. The area of infarcted muscle varies in size but may involve a large part of the anterior wall and apical region, the septum or postero inferior wall. The infarcted area is pale, soft, friable and sometimes almost gelatinous. Hæmorrhagic patches are frequently seen in the necrotic zone and recent thrombi may be adherent to the endocardium beneath the area of infarction, which is sometimes surrounded by a reddish zone of hyperæmia. When the ventricular septum is involved, rupture may occur, leading to direct communication between the right and left ventricles. The papillary muscles are sometimes involved in cardiac infarction and occasionally one or more of the mitral valve chordæ may be fractured. In most cases of recent infarction a diligent search of the coronary vessels reveals a recent thrombus, but in some cases this is not so and it is presumed that intense prolonged ischæmia (acute coronary insufficiency, see p 849) may result in necrosis. In such cases the necrosis is often patchy or in the sub-endocardial layers which are usually preserved in massive cardiac infarction due to acute occlusion.

Microscopical examination of recent cardiac infarction shows that the nuclei of muscle cells disappear first, followed rapidly by the disappearance of the whole cell structure and surrounding vessels and connective tissue. The necrotic mass becomes surrounded by a zone of reactive inflammation with abundant leucocytes and extra vascular red cells. Organisation involving resorption of necrotic cellular material and invasion by new vessels and fibroblasts begins within 7 days. Healing by fibrosis

and contraction of the scar continues for many weeks. In long standing cases of ischæmic disease and cardiac infarction the heart is frequently enlarged. Dilatation is present when there has been heart failure. Hypertrophy of the good muscle is present when there is associated hypertension or valvular disease, it is doubtful whether hypertrophy occurs as a result of ischæmia and infarction alone.

The pericardium is often thickened and adherent over areas of old infarction and the ventricular wall is thin, hard and pale, due to dense fibrous tissue. Layers of organised thrombus are frequently found lining the ventricular cavity beneath the damaged area. Aneurysm formation occurs when an area of old infarction stretches and bulges under the influence of ventricular pressure. The aneurysmal cavity is usually filled with layers of partially organised clot. Calcification occasionally occurs in the scar tissue.

ANGINA PECTORIS

Synonyms—Angina of Effort, Heberden's Angina

Angina pectoris was described by Heberden in 1768, but its relationship to coronary disease was not appreciated until the present century. Angina pectoris is essentially a clinical syndrome of characteristic chest pain produced by increased cardiac work and relieved by rest. The underlying cause in all cases is occlusive disease of the coronary arteries, which is mostly atheroma, sometimes syphilitic coronary ostial stenosis, and very rarely coronary embolism or congenital anomalies of the coronary vessels. Cardiac pain identical with angina pectoris may also be caused by aortic stenosis and less commonly aortic incompetence, it also occurs in patients with severe pulmonary hypertension and rarely in pulmonary stenosis. Anæmia, if severe, may cause cardiac pain, but rarely of the severity met with in coronary atheroma. Angina pectoris is often associated with myxœdema rarely with thyrotoxicosis and frequently with diabetes mellitus and in these conditions coronary atheroma is the underlying cause.

Clinical Features—Paroxysmal chest pain caused by effort and other stimuli is the cardinal feature of angina pectoris. Although the pain varies in intensity, radiation, and the ease with which it is provoked, there is a constancy of the pattern which enables the disease to be recognised from the clinical history in the great majority of patients.

Anginal pain in most cases is situated in the front of the chest and mostly over the sternum. It tends to spread transversely from the sternum to the right and left pectoral regions. Occasionally the area of pain is small and it may be confined to the upper end of the sternum or localised in the left pectoral region. It is more common on the left than the right side of the chest. Anginal pain tends to spread centrifugally to the arms, neck, jaws and epigastrium, the left shoulder and left upper arm are most often involved but frequently both arms are affected, and further spread down to the elbow, ulnar side of forearm and fingers is common. Many patients complain of numbness and a sense of great weakness in one or both arms. From the upper chest pain tends to spread to the neck, lower jaw, gums and teeth, occasionally it is experienced in the arm or jaws at first but in all cases the front of the chest is eventually involved. Less frequently pain is experienced in the epigastrium. Patients may feel that the pain is deep in the centre of the chest and often pain between the scapulae and across the shoulders accompanies the usual sternal pain. The extent of radiation of pain is roughly related to its severity. Ischæmic pain is characteristically described as constricting, crushing, vice like or pressing. Sometimes there is a sensation of a weight on the front of the chest and some patients complain of rawness or burning in the sternal region. The pain is steady during the attack, it does not stab, prick or shoot and is not related to chest movement or respiration.

Physical effort is the most common immediate cause of anginal pain. The first attack may be noticed with unusual effort but sooner or later walking brings on the pain. An increase in pace, running or walking uphill diminish the threshold at which effort induces angina. A recent meal, cold air and worry also cause the pain to appear more readily. In some patients a meal, prolonged conversation, an argument, or any intense emotional situation may induce the pain without physical exertion. Rarely, and when ischemia is severe, attacks of angina may be produced by lying down and, as with left ventricular failure, patients may be awakened from sleep. In such cases there is often a history of an unpleasant dream, but it would seem more likely that posture is responsible for these attacks, which are rapidly relieved by sitting up in bed. When physical exertion is the exciting cause, there is a remarkable constancy in the kind, rate or amount of effort which will probably, if not always, bring on an attack and this also applies in a lesser degree to other exciting causes. Occasionally there is a clear history of a rapid increase in severity of the condition, threshold of onset is progressively lowered, pain becomes more severe and the frequency of attacks is greater. Such a history suggests impending cardiac infarction.

Attacks of angina rarely last for more than a few minutes. The pain rapidly reaches maximal intensity and subsides when the provoking stimulus is removed. In most cases the patient stops walking or slows below the critical point at which pain is produced. In very rare mild cases relief may come in spite of continued effort but in all severe cases pain brings the patient to a complete standstill—this immobility is enforced and is not a voluntary act to relieve pain. Even when pain has been largely abolished by a sympathectomy, a curious sensation is often experienced which demands immediate rest. With advanced disease the attacks may become very frequent being evoked by the smallest effort. Although angina pectoris is essentially paroxysmal sometimes a dull sternal ache persists between the attacks. Occasionally attacks are accompanied by a sense of anxiety out of all proportion to the severity of the pain and sometimes by a sense of impending dissolution.

The facial expression is often strained and anxious and there may be pallor at the time of the attack, but there are no important abnormal signs directly related to an attack of angina, the pulse rate may change—in some patients it is increased while occasionally it is diminished. The arterial blood pressure is usually somewhat increased. A few patients show a general pressor reaction associated with the pain, there is flushing of the face, sweating and a sharp rise of systemic blood pressure. When angina pectoris is due to disease other than coronary athero sclerosis there are associated symptoms and signs of the underlying cause (see appropriate sections).

The electrocardiogram—The electrocardiogram should be obtained in all cases of suspected angina pectoris. There is no close agreement between various investigators concerning the frequency of a pathological electrocardiogram. However if the electrocardiographic investigation includes standard leads, lead III on inspiration, unipolar limb leads and at least three precordial leads, it is probable that 85 per cent of patients will show some abnormality of the tracing. Those patients showing a normal electrocardiogram at rest should have further tracings taken at 2 minute intervals for 6 minutes after moderate exercise. The amount of exercise is graded to the patient's capacity and should never continue after pain has started. It is obviously unnecessary to proceed with exercise tests if the resting electrocardiogram is abnormal. In angina pectoris the electrocardiogram may show such gross changes as left bundle branch block (see p 833) or old cardiac infarction (see p 801) but more often the changes are slight and these are (1) depression of the S T segment by 1 mm or more (2) unusual coving or winging of the S T segment, (3) flattening or inversion of T waves (4) inversion of U waves in left ventricular leads. Any one or all of these changes may be present when the patient is at rest or they may be produced by effort and recede with rest, or be produced by induced anoxemia.

Other investigations—The ballistocardiogram is pathological in a high percentage

of cases of angina pectoris but probably has little to add to the electrocardiogram from the diagnostic point of view

Radiography often shows a normal sized heart but radiographic screening should be routinely carried out

Further investigations are only necessary when disease other than coronary atheroma is the suspected cause, thus renal investigations are indicated for cases associated with hypertension, metabolic tests for those with hypothyroidism and a Wassermann reaction where syphilis is a possible cause

Diagnosis—(1) *The symptom*—Angina pectoris is recognised by the clinical history, the most important features of which are the sternal site of pain, the relationship to effort and relief by rest. The constancy of the type, site and amount of effort required to cause the pain is an important feature of angina. Patients do not tell of other minor symptoms, their concern is with the one pain and they usually remember well the circumstances of a first attack, which is so often indelibly impressed on the mind. The relief of pain by nitrites may be misleading, many neurotics are relieved by drugs through suggestion and the relief of spasm of smooth muscle elsewhere, e.g. œsophago spasm, may be relieved by nitrites. The results of physical examination are not helpful except where the presence of hypertension, and organic heart disease known to be associated with angina, is detected. Even in such cases it is on the characteristic features of the pain that diagnosis is made. The presence of ischæmia of the myocardium is confirmed by an electrocardiogram

(2) *The cause*—A diagnosis of angina pectoris is insufficient, it refers only to a symptom and contains no information concerning ætiology. In all cases a cause other than coronary atherosclerosis should be sought, in males from the age of 30 onwards coronary disease is by far the commonest cause, but in women this is not so. Most of the other causes of ischæmic pain, i.e. aortic stenosis, syphilitic aortitis, anæmia, myœdema and pulmonary hypertension may be diagnosed readily by clinical examination

Other causes of chest pain—There are many causes and types of chest pain. Few should be confused with angina pectoris after a comprehensive history has been obtained by the art of firm interrogation. Pain associated with anxiety or other manifestations of psychoneurosis is the most common source of confusion. Neurotic patients often have numerous symptoms and the pain is usually beneath the left nipple, occasionally it is over the sternum and related to effort, but careful questioning usually shows that the relationship is inconstant or that the pain lasts for hours and comes on after the effort is over. It is frequently related to fatigue, both sexes may be affected and there are often obvious signs of anxiety. The electrocardiogram is normal before and after exercise. Pain arising from the œsophagus may cause difficulty. Here there is rarely any relation to effort although œsophageal pain may have the same quality and distribution as angina pectoris. Hiatus hernia produces a similar spasmic pain, but there is no relation to effort, although a particular posture or particular movement may produce this pain. Hiatus hernia is not uncommonly associated with angina pectoris, both conditions occur with increasing frequency after middle life. Œsophageal spasm, œsophageal arrhythmia and hiatus hernia are diagnosed by radiological investigation. Pain referred from musculo skeletal lesions may superficially resemble angina pectoris, especially if movement is confused with effort. Lesions of the cervical spine such as cervical spondylosis may cause pain over the upper chest and pain in the arms. Lesions of the upper dorsal spine may likewise cause neuritic pain in the front of the chest and a sudden movement of the chest or sneezing may produce it. Often there is no demonstrable musculo skeletal lesion but occasionally there is spondylitis or a prolapsed intervertebral disc. In these referred skeletal pains the electrocardiogram is normal. Especial care must be taken in the diagnosis of shoulder pain associated with chest pain.

Gall bladder disease is said to cause confusion with angina pectoris, these

conditions often coexist and whilst gall-bladder disease may in some way lower the threshold for cardiac pain when there is coronary disease, it does not alone produce chest pain related to effort.

Prognosis—One of the features of angina pectoris due to coronary artery disease is the varied course and uncertainty of outlook. Sudden death or cardiac infarction may occur early in the disease, on the other hand, attacks may subside in frequency and intensity and even completely disappear for years. However, in most cases the malady tends to be slowly progressive and the average duration of life is 8 years, but many live for 15 to 20 years. Hypertension, arrhythmia, diabetes mellitus, excessive weight and a strong family history of degenerative vascular disease adversely influence prognosis. The outlook is worse when attacks are caused by relatively slight exertion or excitement and when the pain is severe, widespread and persistent. A history of increasing severity indicates impending cardiac infarction, and if this episode is survived, subsequent effort pain may be less severe or even absent. Sudden death or cardiac infarction may supervene even in the mildest cases. The outlook for women is better than for men.

Prognosis in angina pectoris is affected by the underlying cause, it is good when associated with conditions which can be treated, such as paroxysmal tachycardia, thyrotoxicosis and anaemia. Cholecystectomy may favourably influence the outlook in cases where gall bladder disease appears to be related to the attacks. When angina pectoris is associated with ventricular hypertrophy due to chronic valvular disease, pulmonary or systemic hypertension, the outlook is usually unfavourable. It is worse when syphilis is the cause of aortitis, coronary stenosis, aortic incompetence and ventricular hypertrophy. A good response to treatment in all cases of angina favourably influences prognosis, especially when life can be modified in such a way that attacks no longer occur.

Treatment—Individual attacks of angina pectoris are relieved by rest. Most patients discover this in the first few attacks and all should be advised to cease exertion as soon as the first suggestion of pain is experienced.

Nitrites specifically relieve anginal pain by causing dilatation of coronary vessels, systemic arterioles are also relaxed, causing a fall in peripheral resistance. Therapeutic doses produce slight hypotension and tachycardia. Glyceryl trinitrate (trinitrin, trinitroglycerin) is the drug of choice, it is cheap, effective, administered in tablet form and is devoid of the more unpleasant side effects caused by amyl nitrite. Fresh tablets of glyceryl trinitrate (gr $\frac{1}{100}$) act in about 2 minutes when chewed and take longer when retained under the tongue. The effect lasts from 15 to 30 minutes. One tablet chewed at the onset of pain is usually effective, more may be taken if necessary. There are no long term toxic effects and patients with angina pectoris should always carry a supply of fresh tablets. When it is necessary to undertake effort which is known to produce pain a tablet should be chewed in anticipation and is frequently effective in preventing the attack. Glyceryl trinitrate sometimes causes a throbbing in the head and rarely a sense of giddiness or faintness.

Amyl nitrite is supplied in silk covered glass capsules, which must be broken and the malodorous vapour is then inhaled—an altogether unpleasant procedure. This drug acts somewhat more quickly than glyceryl trinitrate but the side effects due to vasodilatation are more unpleasant. In view of the hypotensive action of amyl nitrite, it is advised for attacks of angina pectoris associated with a hypertensive reaction, but many find that glyceryl trinitrate is equally effective. Octyl nitrite is volatile and acts quickly but suffers the disadvantages of amyl nitrite. The longer acting organic nitrites should not be used for separate attacks but are said to diminish the intensity and frequency of attacks (see below).

GENERAL MANAGEMENT AND PREVENTION OF ATTACKS—Those situations which cause anginal pain are best avoided. Effort should be confined to levels below that which provokes pain, and if this is not possible, a tablet of trinitrin should be taken

prior to the expected pain. Hurry should be completely eliminated. Arguments, excitement or situations charged with emotional tension should be avoided and a quiet, philosophic attitude to life developed. It is advisable to avoid the spectacle of highly competitive sport, but quiet personal exercise of a steady kind below the level at which pain is caused should be encouraged.

Large meals are best avoided and exercise should not be taken after meals. When there is obesity, weight reduction is advisable, and this should be carried out by a low-fat, low-calorie regime. Weight reduction is most effectively carried out during a period of supervised bed rest in the first instance, when a 1,000 calorie diet may be used and salt restricted to 0.5 g daily if there is associated hypertension. After an initial response the diet can be increased, but in all patients meals should be frequent, never large and low in fat and cholesterol.

Problems concerning hours of work, type of work, leisure time and holidays can only be resolved having due regard for the severity of the illness and individual economic and social responsibilities of the patient. In general it is better to remain in employment, but to reduce the number of working hours and diminish the physical and mental loads where these are heavy.

It is beneficial to have not less than 10 hours in bed per day and to spend most of one day per week in bed. A period of prolonged partial bed rest up to 4 weeks is advisable for patients seen soon after the onset of angina pectoris. Bed rest is also indicated when the disease is increasing rapidly in severity, for this suggests impending cardiac infarction. In such cases when brief attacks of pain begin to occur at rest, anticoagulant therapy (see p. 847) may be used with benefit.

Sedatives are advisable where emotional factors readily produce pain and for patients with secondary anxiety. It is especially important to ensure sound sleep and barbiturates should be freely used.

Tobacco smoking is best stopped altogether, if this can be done without causing too much mental stress.

Alcohol is not contraindicated. It is a sedative and possibly a mild coronary vasodilator. The admissibility of alcohol can be used to offset the withdrawal of tobacco, and even in total abstainers the news that it may be taken comes as relief when it is expected that the physician's advice will be entirely restrictive. An optimistic reassuring attitude should be adopted by the physician at all times.

When attacks are frequent and cause severe restriction of activity, the long-acting vasodilators may be tried. Erythrol tetranitrate and manitol hexanitrate (dose gr $\frac{1}{4}$ to $\frac{1}{2}$) produce a vasodilatation in about 20 minutes which may last for some hours. The results are not impressive but the need for short-acting nitrates may be somewhat diminished. Khellin is extracted from the seeds of *Ammi visnaga*. It causes vasodilation and has been used with some success in angina pectoris. Undesirable side effects, particularly nausea and vomiting, are a disadvantage. Khellin may be given orally or intramuscularly in doses of 40 mg three times a day, this may be increased up to 100 mg doses. Some 50 per cent of patients are improved, fewer trinitrin tablets are used and pain is rather less severe and is caused by a greater amount of effort. There is always great difficulty in assessing the value of therapy in angina pectoris because suggestion, the enthusiasm of the physician and the psychiatric state of the patient play a considerable part in the severity of symptoms.

Tocopherol (vitamin E) has been advocated by some physicians, but the beneficial effect is doubtful and not yet confirmed.

The xanthine group of drugs, especially aminophylline, are often used in the treatment of angina pectoris. There is much disagreement about their value. It is certain that any effect is slight and xanthines, if used at all, should be invariably secondary to the nitrates. Aminophylline (theophylline-ethylene diamine) may be given in doses of 0.1 to 0.2 g four times a day. A suppository of aminophylline at night is well worth a trial for patients having frequent nocturnal attacks. When

early left ventricular failure appears to be associated with angina pectoris, as in patients having nocturnal attacks of pain, sodium restriction and digitalis should be used (see treatment of heart failure, p. 812).

Antithyroid drugs, and in the past thyroidectomy, have been used to induce hypothyroidism and thereby lower the demands on the heart and circulation. It is doubtful whether the serious nature of the treatment is justified. Thiouracil drugs may cause toxicity and constant supervision is needed. Hypothyroidism may be associated with an increase in atheroma and many patients prefer angina pectoris to myxœdema. However, in cases where disability is great and even slight effort is attended by pain, propyl-thiouracil should be tried for a few months in doses of 200 mg. thrice daily at first and later reduced to 100 to 200 mg. daily.

Surgical treatment has been attempted during the last two or three decades. The object has been to cut the sympathetic nerves which conduct pain sensation or to improve the coronary circulation by producing coronary vascular anastomoses. Pain fibres are cut by either dorsal ganglionectomy and stellate ganglionectomy or posterior rhizotomy of the upper five dorsal roots. Some 50 per cent. of patients obtain considerable relief, but mortality is rather high and many patients complain that pain is replaced by an equally unpleasant but indefinable sensation often associated with giddiness which demands immobility.

The creation of an adhesive pericarditis has been carried out by introducing irritants into the pericardial sac in the hope that new vessels will develop between pericardium and epicardium and between end vessels of the coronary circulation. In practice either magnesium silicate or bone dust is used, and the procedure has enthusiastic advocates who claim considerable success. Further experience is necessary before the results of this method can be assessed.

The creation of an effective anastomotic circulation is a more rational procedure but so far results have been disappointing. Various methods have been used. Early attempts, notably by Beck and O'Shaughnessy, involved the suturing of pectoral muscle or omentum to the heart. More recently branches of the internal mammary artery have been directly implanted in the myocardium and the coronary sinus has been anastomosed to the aorta; these latter methods are still in an experimental stage and the operative risks are great.

TREATMENT OF THE UNDERLYING CAUSE.—Unfortunately this is rarely possible but in all cases the aetiology should be reviewed. The treatment for syphilitic aortitis, anæmia, aortic stenosis, myxœdema, thyrotoxicosis and other causes of angina pectoris are described in the section concerned, but in addition to any specific treatment, all cases should be managed along the lines indicated above.

CARDIAC INFARCTION

Synonym.—Myocardial Infarction.

The essential feature of cardiac infarction is acute necrosis of heart muscle. This is usually due to coronary occlusion which in most cases is due to coronary thrombosis, so that these terms have become almost synonymous by common usage. The aetiology of ischaemic heart disease and coronary atheroma has been discussed and similar factors are operative in cardiac infarction. There are no constant conditions which precipitate cardiac infarction; physical exertion and exceptional emotion do not appear to be important, and in many cases the onset is during sleep; it may occur at any time of the day or at any time of the year, but it is somewhat more frequent during winter months.

Cardiac infarction is said to be more common in short, obese individuals, but there is no doubt that it may occur in patients of any physical build or mental type. There are, in fact, no constant common features apart from the great preponderance of the disease in men. Coronary thrombosis is invariably associated with coronary

atheroma, but it is probably not the only ætiological factor, for advanced coronary atheroma is often found in patients who have never had manifestations of ischæmia, furthermore there is evidence from necropsy studies that whilst cardiac infarction has increased in frequency during recent years, coronary atheroma has remained unchanged, it is thus possible that an altered state of blood coagulability may be concerned with the pathogenesis of coronary thrombosis in addition to the presence of coronary atheroma. Coronary embolism, usually due to bacterial endocarditis, is a rare cause of acute occlusion and cardiac infarction.

Hypertension is frequently associated with coronary disease and it appears that coronary atheroma is more likely to become manifest as ischæmic heart disease when hypertension is present. Hypertension may be a factor in the pathogenesis of coronary atheroma, but it is also possible that both conditions are the result of the same common factors, which remain unknown.

Gall bladder disease occasionally appears to precipitate ischæmic heart disease and it is possible that reflexes from the alimentary canal lower the threshold for cardiac pain. However, there is no evidence that gall-bladder disease or any other disturbance of the alimentary system is closely related to the cause of ischæmic heart disease.

Clinical Features—*Pain* is the most prominent frequent symptom and it may be associated with shock or acute heart failure. There are prodromal symptoms in many cases. Brief attacks of pain may occur during the preceding 24 to 72 hours and sometimes there is a general feeling of malaise for a few hours before the major attack of pain. Patients having a long previous history of angina pectoris may recognise an increase in its severity during the preceding weeks and a few patients give a short history of angina pectoris which, from its onset, increases in frequency and intensity until brief attacks of pain at rest may herald a major attack of infarction. Many patients in this group seek medical advice before infarction occurs.

The onset of pain is rapid and it is independent of any exciting cause, it may occur at any time of the day or waken the patient from sleep. The maximal intensity of pain is soon reached, it is a steady pain and may be mild or of agonising intensity—among the severest of pains experienced by man. Its site, radiation and quality is the same as occurs in angina pectoris (see p. 837), but it tends to be more severe and lasts for hours or even days. Few patients remain motionless as in angina pectoris, most become restless and adopt various positions in an attempt to get relief, some walk about and I have known one patient who ran "to work off" the pain, and another who proceeded to exercise in a gymnasium in order to relieve the "acute rheumatism" in his chest. None of these manoeuvres brings relief from the steady intense pain. Painless cardiac infarction is probably very rare. In some cases extreme shock and unconsciousness may be responsible for the early absence of pain, which, however, appears when the syncopal state passes off. The pain of past cardiac infarction may be forgotten when there is advanced cerebral vascular disease.

Shock is a common feature of cardiac infarction and all degrees occur, from those with symptoms of dizziness, weakness or faintness, sweating and vomiting, to those with severe degrees of shock which dominate the whole clinical picture. In severe cases there is great weakness, postural syncope may be the first symptom and this may be recurrent unless the patient is recumbent. The skin is pale, cold and moist, the face is greyish, drawn and anxious, and the mind is often clear. The skin of the extremities shows extreme vaso constriction, being white or patchily cyanosed. The blood pressure is low and the pulse pressure may be so diminished that a radial pulse cannot be felt. Shock may persist for hours or even days. Pain, left ventricular failure or a general improvement may emerge as the shock state passes off.

Heart failure may occur alone or in combination with pain or shock at any time during the history of cardiac infarction. In the early stages of the disease heart failure usually appears as acute left ventricular failure, indeed the first symptom

may be an acute attack of cardiac asthma or even pulmonary œdema. Pain is usually present but the patient is sometimes overwhelmed by dyspnoea and a history of pain may not be obtained until later. Congestive cardiac failure may develop at any time, but usually after an interval of a few days. Cheyne-Stokes respiration is often present.

Nausea and vomiting are common features of cardiac infarction and may be combined with upper abdominal discomfort or epigastric pain. Morphine is often responsible for gastro-intestinal symptoms. Arrhythmias frequently develop in cardiac infarction, extrasystoles and brief episodes of auricular fibrillation being the commonest, but most patients are unaware of the irregularity and few complain of palpitation. Auricular or ventricular tachycardia may be paroxysmal or persistent and are often responsible for serious deterioration.

Cardiac infarction may or may not produce physical signs. Even with prolonged severe pain there may be no abnormal findings. Fever is common. It is of mild degree and lasts for a few days from the first or second day of the attack. A moderate leucocytosis and elevation of the erythrocyte sedimentation rate is usual. Tachycardia is often more than can be accounted for by fever and the arrhythmias mentioned above, including heart block, may be detected by examination of the radial arteries and jugular pulses.

Pericardial friction occurs early in some 10 to 15 per cent of cases, especially in those with anterior infarction. It is often fleeting but may persist for days and indicates accompanying pericarditis. *Triple rhythm* due to the addition of a diastolic filling sound (third heart sound) is often audible. It may produce a protodiastolic or presystolic cadence of sounds, depending on the heart rate. It indicates severe muscle damage.

Shock is indicated by pallor, sweating, peripheral constriction and hypotension. When shock is absent, blood pressure may rise initially but tends to fall after 24 to 48 hours, and it may return to normal or near normal levels after a varying interval of days or weeks.

Heart failure is indicated by dyspnoea, orthopnoea, Cheyne Stokes respiration or pulmonary œdema. A rise of jugular venous pressure is common but œdema, ascites and hepatomegaly are not usually seen in the early stages. Any of the signs of heart failure may be encountered at any stage of the illness, but the signs of shock are early. The signs of complicating thrombo embolism should be sought and may appear at any time, but commonly in the first 3 weeks.

The electrocardiogram—The electrocardiogram is of great diagnostic value. It is always abnormal in cardiac infarction although rarely it may remain normal for a few hours after the onset of pain. The ventricular complex is altered in three ways (see p 801). (1) Large primarily negative waves (Q waves) appear in leads recording the main left ventricular potentials, i.e. where R waves existed before. These pathological Q waves are usually more than 0.04 sec. duration and may replace all of the QRS or be followed by the remnants of an R wave. The development of Q waves indicates muscle death, hence the change is usually permanent and is highly specific since coronary disease is almost always the cause of circumscribed myocardial necrosis. (2) Elevation and coving of the S-T segment in leads facing the damaged area (and reciprocal depression of the S-T segment in remote leads) are due to superficial injury involving the epicardium and pericardium. S-T elevation is maximal in the early phases of the attack and subsides after a few days. S-T changes are not as specific for cardiac infarction as Q waves, since the same changes occur in pericarditis from other causes. Persistent elevation of the S-T segment may be due to the development of a ventricular aneurysm. (3) Inversion of the T wave in leads where it is normally positive is usual in cardiac infarction. In the earliest days of the attack S-T elevation may be great and the isoelectric interval reached without the development of a separate T wave, however, sharp inversions of the T waves appear as the S-T elevation subsides. I wave inversion mostly occurs in combination with Q waves.

and with S T changes in cardiac infarction Isolated T wave changes are not specific and occur as the result of many varied physiological and pathological changes in the muscle, however, when assessed with the clinical features, flattening and inversion of the T wave have great diagnostic value The T waves may become positive after recovery and healing of cardiac infarction

These pathological changes occur in leads related to the left ventricle and maximally in those "facing" the area of infarction, so that it is often possible to determine approximately its site and size (see p 802) *Anterior infarction* is indicated by Q, S-T and T wave changes in anterior chest leads and in lead I When the septum is involved, complete Q waves also occur in right anterior chest leads *Posterior (or inferior) infarction* is indicated by the finding of Q, S-T and T wave abnormalities in leads from the left leg, i.e. in leads II, III and VI, which record potentials in the field facing the diaphragmatic surface of the heart *Lateral infarction* is diagnosed when changes are found in the extreme left chest leads, i.e. V7, CR7 and VL These changes may occur alone or in combination with an anterior or posterior pattern

Complications—Thrombo embolic phenomena occur in more than one-third of necropsy examinations and are a clinical problem in some 15 per cent of cases Phlebothrombosis in the leg is the most common and is responsible for episodes of pulmonary infarction and for massive pulmonary embolism Systemic emboli may involve any organ and arise from ventricular mural thrombi, however, there is much evidence to suggest that arterial thrombosis in the affected organ is often responsible Cerebro vascular episodes are common

The infarcted area of myocardium may bulge, producing a local aneurysm which, if large enough, causes a diffuse pulsation of the chest wall Occasionally there appears to be a double apex, that due to the aneurysm is usually above and internal to the true apex, and a see saw like movement occurs between the two pulsations Ventricular aneurysms develop soon after the episode of infarction, which is usually of the anterior variety, but they do not necessarily influence the outcome The cavity of the aneurysm often becomes partially obliterated by organised clot Final diagnosis depends on radiological examination, a hump or bulge on the left ventricular silhouette which swells in systole is diagnostic The electrocardiogram shows the changes of cardiac infarction

Rupture of the heart at the site of the infarct is not uncommon, hæmopericardium follows and may cause sudden death When the ventricular septum is infarcted, an internal rupture occasionally occurs, producing a left to right shunt and ultimately causing heart failure The development of a loud systolic murmur in the mid-pericardium, associated with a rise of venous pressure, is suggestive of a ruptured septum

"Frozen shoulder" and "the shoulder hand syndrome" sometimes develop after cardiac infarction Pain frequently occurs in either shoulder at variable periods from a few weeks to a few months after an attack of cardiac infarction, and in severe forms the shoulder may become stiff, painful and ultimately almost immobile Less commonly the hand becomes stiff, swollen or shows trophic changes in the skin The fingers become smooth and pale, resulting in a scleroderma like condition Spontaneous recovery after a variable period is usual

Prognosis—Cardiac infarction is an unpredictable disease Sudden death may occur at any time and in the mildest cases, whilst others who are gravely ill during the acute stage may survive to live many years There is no agreement about mortality rates but probably 25 per cent die in the first attack, however, this figure is considerably lower for those receiving early, competent treatment The greatest mortality occurs in the first 48 hours and remains high during the first 7 to 10 days After 3 weeks there is an excellent chance of recovery from the immediate illness provided that there are no signs of heart failure

Prognosis is adversely affected by increasing age, but sudden death from cardiac

infarction under the age of 40 is not uncommon. The prognosis for patients with a mild attack is relatively better than for those with symptoms and signs in addition to pain. The persistence of the shock over 24 hours is a grave sign and few recover when shock continues for more than 2 days. The early development of congestive heart failure is serious, however, many patients show a slight rise in venous pressure or signs of mild left ventricular failure for a few days, which does not necessarily affect the outcome. The disappearance of triple rhythm during the early weeks indicates improving ventricular function and a better prognosis than in those patients with a persistent third heart sound. Transient arrhythmias are common and prognosis is not adversely affected, but a persistent irregularity, especially when due to multiple ventricular ectopic beats, ventricular tachycardia, heart block or auricular fibrillation, is of grave significance.

Pulmonary infarction and other thrombo-embolic manifestations often cause deterioration and may adversely affect the outcome at any time during the first 3 weeks.

Hypertension and preceding angina pectoris do not materially alter prognosis, but a history of previous cardiac infarction does. The site, duration and intensity of pain, unless associated with shock, does not affect prognosis, nor does the anatomical site of the cardiac infarction.

As in all forms of ischemic heart disease, women do better than men. The outlook improves with each week that passes free of complications, but after recovery from the acute illness, the ultimate prognosis depends on many factors. Prognosis is favourable when heart failure, cardiac enlargement, triple rhythm, hypertension, diabetes mellitus, obesity and angina pectoris are absent, and when the electrocardiogram shows recovery of the S-T segments and T waves. Under such circumstances many years of good health are probable, but the development of a further attack of infarction is always possible and unpredictable.

Treatment—Treatment of cardiac infarction is based on four principles: (1) The relief of pain, (2) the treatment of shock and heart failure, (3) the reduction of cardiac work and (4) the prevention and treatment of complications. Immediate rest is indicated at the onset and the patient should be moved to bed as soon as possible.

Morphine is usually required to relieve the pain, but it should not be given routinely, and when the pain is slight a milder analgesic may be sufficient. Morphine should be given subcutaneously in doses of gr $\frac{1}{4}$ to $\frac{1}{2}$, and if the pain is especially severe gr $\frac{1}{4}$ in 5 ml of sterile water may be given slowly into a vein, followed by subcutaneous doses of gr $\frac{1}{4}$ at intervals of 1 to 2 hours if severe pain persists. Vomiting, depression of respiration, and disturbances of the bowel are often due to morphine; synthetic morphine substitutes, which have few side effects, may therefore be used with advantage after the initial relief of pain.

Shock passes off under the influence of rest and morphine in most patients, but in some it is more severe and persistent. When acute hypotension is responsible for giddiness or syncope, patients must be nursed flat unless left ventricular failure appears when a more upright posture is necessary. Persistent shock carries a very high mortality, transfusions of glucose, plasma and blood have been advocated but they are of little value and may cause acute pulmonary oedema. Adrenaline and ephedrine raise systemic arterial pressure but tend to cause ventricular tachycardia or ventricular fibrillation and should not be used. The newer pressor amines act directly on peripheral vessels without increasing myocardial irritability and should be used if the shock state persists for more than 24 hours. Noradrenaline may be given as an intravenous drip infusion, sufficient dilution being obtained by adding 4 ml of 1,000 noradrenaline to a litre of isotonic 5 per cent dextrose. If hypotension persists the concentration of noradrenaline may be increased to avoid the administration of too great a volume of fluid. The infusion may be continued for hours or days and its rate, concentration and duration judged by therapeutic effects.

Heart failure of any type and severity should be treated with a low salt diet and mercurial diuretics. Aminophylline given as a suppository at night may help to control nocturnal attacks of dyspnoea. Digitalis should be used for congestive heart failure in cardiac infarction but it is advisable to give other methods a trial first unless the severity of the condition demands its immediate use. (For treatment of heart failure, see p 812.)

Arrhythmias are often transient and do not then require special treatment. When extrasystoles are frequent quinidine in doses of gr 3 or 5 four times a day may abolish them and prevent the development of a more serious arrhythmia. Ventricular tachycardia requires immediate treatment, 5-gr doses of quinidine by mouth are given every 2 hours and if there is no response in 12 hours, the dose should be doubled. Intravenous quinidine or procaine amide may be used in the most serious cases, and, where possible, administration should be checked by serial electrocardiograms so that the drug may be discontinued immediately on restoration of normal rhythm (see p 828 for details).

When pain and shock have been relieved, a full assessment of the patient's condition and home circumstances can be made. Gravely ill patients with shock or heart failure are best treated in hospital, others may be treated at home provided that there is freedom from domestic and business worries and adequate nursing help is available.

Most patients require from 4 to 6 weeks bed rest depending on the severity of the attack. From the physical point of view, the difference between complete and modified bed rest is slight, but morale and mental rest are benefited by the less exacting regime. Complete bed rest also increases the risk of peripheral thromboembolism. The recognised hazards of prolonged complete bed rest have led to the advocacy of armchair treatment during recent years. This method has its dangers and there appears to be no sound reason for abandoning bed rest provided that it is intelligently carried out. It is therefore recommended that (1) all cases rest in bed for at least 4 weeks and ideally none should return to work before 12 weeks. (2) Mild and moderate cases with no shock, no heart failure, no cardiac enlargement are allowed to use a commode, feed, wash and shave themselves and sit out of bed for short periods. After the third or fourth week activity should be steadily increased. (3) More seriously ill patients should be rested in bed for 6 weeks or more if necessary. (4) Shocked patients should be nursed recumbent until the arterial pressure rises whilst those with heart failure should be nursed in a more upright position. It is emphasised that at all stages the clinical condition of the patient should determine the nursing regime, the length of rest and the rate of convalescence.

Diet—It is advisable to reduce the diet below 1000 calories daily for the first week in all cases. Thereafter more food is allowed but the separate meals should be small. Salt should be restricted to less than 1 g daily in all patients with hypertension or any evidence of heart failure.

Constipation may become a problem and strenuous defaecation should be avoided by the use of liquid paraffin. Acute retention of urine is not uncommon in the elderly, and it is often advisable to allow elderly patients to sit out of bed for micturition during bed rest for cardiac infarction.

ANTICOAGULANT THERAPY—In a disease where intravascular clotting is an essential part of the pathology and where thromboembolism is responsible for most of the complications leading to a high morbidity and mortality, there are strong theoretical reasons for using anticoagulant therapy and there is now abundant evidence of its value in the treatment of thromboembolic disease. The aims of anticoagulant therapy in cardiac infarction are the prevention of peripheral venous thrombosis and consequent pulmonary embolism, the prevention of intracardiac mural thrombosis and consequent arterial embolism and the prevention of further thrombotic occlusion in coronary vessels. It is probable that these aims are in part achieved without undue

risk of hæmorrhage if anticoagulant treatment is correctly regulated in an institution with adequate pathological services. Anticoagulant therapy should be used for cases of cardiac infarction where there is continued shock, heart failure or evidence of extensive muscle damage as judged by fever, sedimentation rate and the electrocardiogram. It is not indicated in mild cases and when there is a possible pre-existing source of hæmorrhage, e.g. peptic ulcer and cirrhosis of the liver. In most cases where urgent treatment is indicated, heparin is used for 48 hours and one of the oral preparations for reducing blood prothrombin is administered concurrently and then continued for 4 to 6 weeks. In less urgent cases the heparin may be omitted.

Heparin is the best anticoagulant drug available. It is effective within minutes of intravenous injection and when discontinued the coagulability of blood returns to normal in a short time. The necessity for frequent parenteral administration and its high cost are disadvantages. Administration is regulated by estimates of the coagulation time which should be prolonged to two or three times the normal. For short term use before one of the coumarin drugs is effective, heparin is best given by intravenous injection in doses of 50 mg (5 000 units) every 4 hours. Intramuscular injections may be given twice daily for a prolonged period in doses of 100 to 150 mg, and the immediate pain of injection may be abolished by the addition of 2 ml of 1 per cent procaine to 1 ml of heparin, but delayed discomfort and extensive bruising at the site of injection are common and a serious disadvantage. Overdosage with heparin may be corrected immediately by 50 mg of protamine sulphate given intravenously or by a transfusion of whole fresh blood.

Coumarin drugs affect the production of prothrombin by the liver and thereby prolong the prothrombin time of plasma, but they do not materially alter the coagulation time of whole blood. These drugs have the great advantage of being effective when given by mouth. Disadvantages are the necessity for control of administration by frequent estimation of prothrombin time, their relatively slow action and slow elimination. These drugs should not be used in the presence of liver disease, kidney disease or a serious blood dyscrasia.

Dicoumarol has been largely superseded by ethyl biscoumacetate (Tromexan) and phenylindanedione (Dindevan) which have a more rapid action and are more easily controlled. A daily estimation of prothrombin time should be made before the next dose is administered. Prothrombin time is estimated by the Quick method in which oxalated blood plasma is mixed with an excess of calcium ion and an excess of thromboplastin. The clotting time is prolonged in proportion to decrease in concentration of prothrombin. In all cases the prothrombin time should be estimated before treatment; the normal is between 12 and 17 seconds and a safe therapeutic level is achieved when this is prolonged from 2 to 2.5 times, which corresponds to a prothrombin level of 15 to 30 per cent. Average doses for patients of medium weight are as follows: Dicoumarol 300 mg first day, 200 mg second day and thereafter 50 to 200 mg depending on prothrombin times. Ethyl biscoumacetate 1500 mg first day and thereafter 300 to 900 mg. Phenylindanedione 200 mg on the first day and 50 to 150 mg thereafter. Division of the daily dose produces a more even lowering of the blood prothrombin.

Inspection of a daily urine specimen for red cells is a useful adjunct to control by prothrombin time. Hæmorrhage due to overdosage is treated by transfusion if necessary. Vitamin K₁ oxide is an effective antidote; prolonged prothrombin time may be raised in 6 hours by an intravenous or more slowly by an oral dose of 200 mg. Some physicians advocate the use of anticoagulants over long periods with weekly estimations of prothrombin time. The results are difficult to evaluate and the hazards considerable.

TREATMENT OF COMPLICATIONS—*Phlebothrombosis* in the legs with or without accompanying pulmonary infarction is an indication for anticoagulant therapy (see above). The treatment of peripheral arterial embolism or thrombosis depends on

the site and severity of the resulting ischaemia (see p. 925). There is no treatment for ventricular aneurysm.

Shoulder-hand syndrome causing pain and stiffness tends to become permanent but many mild cases recover spontaneously or with the help of physiotherapy. A short course of cortisone in doses of 50 to 100 mg. by mouth cures some more resistant cases; when this fails, procaine block of the stellate ganglion is indicated.

MANAGEMENT AFTER THE ACUTE ATTACK.—Convalescence should be from 4 to 6 weeks. The degree of activity permitted thereafter depends entirely on the assessment of the clinical condition and its relation to the social and economic status of the patient. Many patients are able to return to their previous occupations and should be encouraged to do so. It is advisable to continue with small meals if there is a tendency to obesity. Smokers should reduce their tobacco consumption. Alcohol should not be prohibited. It is customary to advise moderation in all things and to reduce physical activities, but most patients are benefited by following their personal inclinations for work, exercise and leisure activities. There is evidence that restriction of activities beyond that imposed by diminished cardiac reserve not only fails to prevent further deterioration but may even hasten it. Angina of effort or heart failure require treatment and often cause permanent incapacity. The physician should maintain an attitude of optimism tempered by intelligent explanation and above all he should never cause unnecessary anxiety.

ACUTE CORONARY INSUFFICIENCY

Acute coronary insufficiency is not a clearly defined clinical syndrome; the term is used to indicate an acute disparity between the supply of oxygen and the demands of the myocardium, which is more prolonged than in angina of effort. On the other hand it excludes the clinical syndrome of acute coronary occlusion with cardiac infarction which is more severe and permanent. In acute coronary insufficiency the emphasis is on sudden abnormal increased demand or a sudden fall in blood supply due to factors other than complete coronary occlusion.

Pathology.—There is usually some degree of coronary atherosclerosis ranging from normal to severe, but there is no fresh thrombotic occlusion. Subendocardial necrosis or small patches of necrosis in deep layers of the muscle are usual, but massive necrosis involving pericardium and endocardium is not seen. Mural thrombosis and peripheral emboli do not occur.

Aetiology.—The sudden diminution of blood supply or greatly increased cardiac work required to produce acute coronary insufficiency is usually due to some degree of coronary disease associated with one or more of the following conditions: (1) Haemorrhage and other causes of shock and hypotension, (2) acute heart failure, (3) asphyxia and especially carbon monoxide poisoning, (4) acute severe pulmonary disease, (5) pulmonary embolism, (6) unusually severe effort or great emotional stress, (7) paroxysmal tachycardia and (8) acute hypertension.

Symptoms.—Pain is the usual symptom as in other manifestations of cardiac ischaemia; it lasts longer than in angina pectoris and it may occur under a variety of circumstances depending on the immediate cause. Shock, heart failure, fever and leucocytosis are not present. There are no signs of acute coronary insufficiency *per se*, but the signs of an associated precipitating cause may be present.

The electrocardiogram.—The electrocardiogram shows similar changes, but of greater magnitude than those found during an attack of angina pectoris. Great depression of the S-T segments in left ventricular leads is usual. T waves may remain flat or inverted for a few days after the attack. Pathological Q waves do not occur.

Prognosis largely depends on the nature of the immediate cause and whether there is evidence of severe coronary artery disease. The same general factors determine prognosis as for angina pectoris of effort.

Treatment.—During the attack trinitrin should be given as for angina pectoris (see p. 840), but it is usually ineffective and morphine may be necessary for the relief of pain. Heparin 50 mg. should be given intravenously and continued in similar doses every 4 to 6 hours for 48 hours. A full course of anticoagulant therapy should be given in those cases where a history of increasing angina precedes the attack of insufficiency and therefore suggests impending infarction. The precipitating cause, *e.g.* anæmia or hypertension requires treatment. A short period of bed rest is advisable.

HYPERTENSIVE HEART DISEASE

Heart disease is the cause of death in approximately 75 per cent. of patients with established high blood pressure. In the great majority of cases the hypertension is of the essential and so-called benign variety. The transitions from asymptomatic systemic hypertension to compensated cardio-vascular hypertrophy and final decompensation is slow and mostly insidious, though sometimes interrupted by more or less acute cardiac or cerebral episodes; the point at which the heart becomes diseased is usually indefinable. The subject of hypertension is dealt with elsewhere.

Ætiology and Pathology.—The ætiology of hypertension is discussed on pp. 907, 908. Systemic hypertension is due to an increased total peripheral resistance with a normal cardiac output; the work of the left ventricle is increased, which leads to compensatory hypertrophy, and in the course of time dilatation of the ventricle occurs.

Disease of the heart in hypertension is essentially disease of the left ventricle. The ultimate failure of compensatory hypertrophy is probably due to failure of the coronary circulation to meet an increasing demand. Hypertension appears to accelerate the development of coronary atheroma which is present in all cases of long-standing hypertensive heart disease.

At necropsy there is hypertrophy of the left ventricle and the whole arterial system. In the majority of cases there is coronary atheroma and the myocardium shows varying degrees of ischæmic damage ranging from widespread fibrosis to more localised areas of infarction.

Clinical Features.—Cardiac symptoms are absent during the compensated stages of hypertension unless coronary sclerosis causes angina pectoris (see p. 837). During the phase of decompensation the symptoms are those of left ventricular failure and congestive cardiac failure (see p. 806). The onset of heart failure may be shown by increasing effort dyspnoea or by paroxysmal dyspnoea which is frequently of the nocturnal variety. Cardiac pain is often present and symptoms suggesting cardiac infarction may precede those of heart failure.

Examination during the compensated phase of hypertension shows varying degrees of arteriopathy in the fundus oculi, thickening of radial and brachial arteries, an apical impulse suggesting left ventricular hypertrophy, a loud second heart sound, sometimes an auricular gallop sound, occasionally an aortic diastolic murmur and always arterial hypertension. When heart failure has developed there is usually cardiac enlargement, a less forcible apex beat which, however, retains some of the sustained heave of hypertrophy, triple rhythm or a summation gallop, a variable apical systolic murmur due to functional mitral incompetence, together with the signs of pulmonary or systemic congestion in varying degrees. The blood pressure usually remains elevated, but as heart failure increases, the pulse pressure falls due to a greater drop in systolic pressure than in the diastolic level. Pulsus alternans may be present and Cheyne-Stokes respiration is common in the late stages. Auricular fibrillation occurs in about 25 per cent. of patients with hypertensive heart failure. In attacks of severe left ventricular failure and in the terminal stages of congestive cardiac failure, extreme peripheral constriction may occur.

Radiographic examination reveals varying degrees of pulmonary congestion when there are symptoms of left ventricular failure. The aorta tends to become "unfolded", causing a widening of the superior mediastinum, the aortic "knob" is unduly prominent and there are often scattered flecks of calcification in the wall. The left ventricle is enlarged and best seen in the left oblique view.

The electrocardiogram shows varying degrees of left ventricular hypertrophy associated with ischaemic changes. Characteristically the R waves in lead I, VL and V5 to V7 are tall and associated with some degree of S-T depression and T wave flattening or inversion in the same leads. In late stages left bundle branch block is common or the R waves become lower in voltage (see electrocardiogram of left ventricular hypertrophy, p 800).

Diagnosis depends on the finding of raised blood pressure together with the signs of cardio vascular hypertrophy. Gross hypertrophy of the left heart in the absence of the signs of valvular disease is generally due to systemic hypertension. When the signs of heart failure have supervened diagnosis may be more difficult, since the arterial tension tends to fall and the powerful thrust of a hypertrophied left ventricle diminishes. However, in such cases the diastolic tension usually remains elevated, whilst retinopathy and thickened brachial vessels indicate long-standing hypertension. Systolic murmurs may suggest organic mitral incompetence but the raised arterial tension and the clinical and electrocardiographic evidence of gross left ventricular hypertrophy indicate the true nature of the condition. Similar criteria serve to distinguish the cause of an early diastolic murmur associated with severe hypertension from that due to organic aortic incompetence. Angina pectoris associated with hypertension must be differentiated from cardiac pain due to other causes.

Prognosis—During the compensated stage of hypertension the prognosis is worse in males than in females, and is adversely affected by high diastolic levels of pressure, evidence of myocardial disease and impaired renal function. When breathlessness develops the prognosis depends on the degree of cardiac damage, the presence of cardiac pain and evidence of ischaemia are adverse factors and triple rhythm, great cardiac enlargement, pulsus alternans and attacks of paroxysmal dyspnoea, occurring in spite of treatment, are of grave import.

Treatment is required for the hypertension and for heart failure when this is present. The treatment of hypertension is discussed on pp 911, 916. It is emphasised that attempts to lower blood pressure with the various hypotensive agents and a low salt diet should be made after the development of heart failure or even when there is evidence of ischaemic disease in the myocardium, for hypertension is the fundamental error responsible for the disease. Heart failure should be treated on the lines indicated on p 812. Regular periods of rest are advisable and an attack of cardiac asthma should be followed by a few days of bed rest. A low sodium diet (see p 812) is probably the most satisfactory method of controlling both hypertension and heart failure and the action of the methonium halide drugs is potentiated by a low sodium régime. Acute left ventricular failure is best treated with morphine, aminophylline, oxygen if there is central cyanosis and a mercurial diuretic, a venesection of 250 to 500 ml should be carried out if other methods are not rapidly effective, parenteral methonium halide has been tried with good effect in acute left heart failure, but further experience is necessary before this treatment can be satisfactorily assessed. Digitalis (*digitalis folia* gr 1 twice daily) should be given to patients with hypertensive heart failure and maintained indefinitely irrespective of rhythm.

PULMONARY HEART DISEASE

Synonym—Cor Pulmonale

Pulmonary heart disease may be defined as a disorder of the right heart, consequent upon disease of the lungs and of the pulmonary vasculature. It may be subdivided

into acute, subacute and chronic forms. Chronic pulmonary heart disease is common and may be due to lung disease, including bronchitis and emphysema, fibroid lung and pneumoconiosis, to vascular disorders of the lungs or to kyphoscoliosis. Acute pulmonary heart disease is due to massive pulmonary embolism and the subacute form to lymphatic or embolic carcinomatosis.

ACUTE PULMONARY HEART DISEASE

Synonym—Acute Cor Pulmonale

Definition—Acute pulmonary heart disease may be defined as a cardiac and circulatory disturbance resulting from rapid obstruction of the pulmonary circulation by one or more massive emboli.

Ætiology.—The immediate cause is sudden obstruction of the pulmonary artery by a large clot, which has become detached from its site of formation either in the systemic veins or in the right heart. Prolonged bed rest predisposes to the formation of clots, particularly in the leg veins. The thrombi in the calf muscle veins, giving rise to pulmonary emboli, may be locally asymptomatic or give rise to only minor symptoms (phlebothrombosis) although sometimes there is local tenderness, swelling and œdema. Pulmonary embolism may occur after operations, especially pelvic and abdominal, fractures and other serious injuries, and is most common in the second and third post-operative weeks. It may follow childbirth. Chronic congestive heart failure may be complicated by pulmonary embolism, since the poor peripheral circulation encourages the formation of clots, but pulmonary embolism is also associated with heart disease without failure, especially cardiac infarction, where reduction of clotting time seems to be a predisposing factor. It may occur in patients with carcinoma, especially of the stomach, and with hæmatological diseases. The act of straining at stool may sometimes be the immediate precipitating cause of displacement of the clot into the circulation.

Pathology—The deep veins of the calf muscles are the commonest source of pulmonary emboli. Less commonly the pelvic veins may be the source or the chambers of the right heart.

Pulmonary emboli causing severe cardiac and circulatory disturbance are large and obstruct the main pulmonary artery and its branches. The large size of the embolus is caused by coiling up of a long thrombus into a compact mass after detachment from its site of formation. A common site of lodgement is the bifurcation of the pulmonary artery with complete occlusion of one branch and partial occlusion of the other. In other cases, in which death rapidly follows the symptoms of embolism, complete or almost complete occlusion of the main pulmonary artery has taken place. The obstructing pulmonary embolus may or may not be all of the same age, being in some cases formed of repeated smaller emboli and in others enlarged by local thrombosis. Smaller pulmonary emboli, insufficient to obstruct the main pulmonary arterial trunk, seldom give rise to serious general cardio vascular disturbances, although they often cause pulmonary infarction.

If the patient survives the initial pulmonary embolism, pulmonary infarction may develop, depending on the site and size of vessel obstructed and the collateral circulation to the segment of lung involved. Embolism is more likely to give rise to infarction in the presence of pulmonary venous congestion from heart failure. Acute pulmonary heart disease however usually occurs without the development of pulmonary infarction since the patient may die before the infarct develops.

The cardiac and circulatory effects of massive pulmonary embolism are due to mechanical circulatory obstruction and to myocardial ischæmia. It has been estimated that in order to cause circulatory embarrassment, 50 to 70 per cent of the cross sectional area of the pulmonary arterial tree must be cut off. When this occurs the output from the right heart is diminished with diminution of venous return to the

left heart and consequently the left ventricular output also falls. At the same time, acute right heart strain develops with dilatation of the right heart and a rise in systemic venous pressure. Myocardial ischaemia resulting in subendocardial necrosis, most severe in the left ventricle, is probably the result of diminished coronary flow (i.e. acute coronary insufficiency) resulting from a fall in left ventricular output and systolic pressure, associated with arterial anoxaemia, due to pulmonary asphyxia. Reflex coronary arterial spasm may also play a part in the production.

Symptoms.—The onset of massive pulmonary embolism is sudden. In some cases, however, smaller emboli precede the massive embolism and in these premonitory symptoms may be present.

The patient often complains of chest pain, frequently very severe, similar in type and distribution to that of cardiac infarction. This is accompanied by acute dyspnoea or tachypnoea. In addition there may be faintness, dizziness, restlessness, mental apathy or convulsions. Sometimes the pain is abdominal rather than substernal. Occasionally there is haemoptysis and in some palpitation from an associated paroxysmal arrhythmia. The symptoms vary widely from case to case and may be relatively mild.

On examination there are usually signs of acute circulatory failure and shock, with a rapid, thready pulse, low blood pressure, pallor, coldness and sweating. In some cases deep black blue cyanosis may be present from pulmonary asphyxia, which is probably reflex in origin. In contrast to the systemic hypotension, resulting from inadequate venous return to the left ventricle, in the right heart there are signs of pulmonary hypertension with systemic venous congestion. Triple rhythm, best heard at the left sternal edge or in the epigastrium is often present. The pulmonary second sound may be accentuated. There may be dilatation of the pulmonary artery, with a systolic murmur and thrill in the pulmonary area. The jugular venous pressure is raised and often associated with acute engorgement of the liver.

If the patient survives the massive pulmonary embolus, signs of pulmonary infarction may develop. There is usually pyrexia and leucocytosis; there may be pleural pain related to the side of the infarction; there may be cough with expectoration of bright red frothy sputum. Examination may reveal signs of consolidation over the infarcted area, sometimes accompanied by a pleural rub and there may be a pleural effusion, which on diagnostic aspiration is found to be blood stained. The clinical picture, however, varies considerably and neither pain, cough nor haemoptysis is necessarily present.

The *electrocardiogram* in massive pulmonary embolus usually shows a deep S wave in standard lead I and a Q wave with inversion of the T wave in lead III. In the V leads there is inversion of the T wave from VI to V4, while in some cases transient right bundle branch block may develop. These signs may persist for days or weeks. With smaller emboli on the other hand, the electrocardiogram usually remains normal.

Radiography.—The hilar shadows may be prominent and the main pulmonary artery large. In addition there may be evidence of pulmonary infarction with a triangular, ovoid or irregular shadow in the lung fields, often accompanied by a pleural effusion.

Diagnosis.—Collapse, precordial pain, dyspnoea, tachycardia and cyanosis in a patient confined to bed after an operation, delivery or during a medical illness should at once suggest the diagnosis of massive pulmonary embolus. The diagnosis becomes even more probable if signs of phlebothrombosis or thrombophlebitis are present in the veins of the calf muscles. If added to this there are signs of right heart strain with elevation of the jugular venous pressure and characteristic electrocardiographic changes then the diagnosis of acute pulmonary heart disease is established.

The differential diagnosis from cardiac infarction may be difficult since pulmonary embolus may complicate cardiac infarction and since either may occur post-operatively. The electrocardiogram is usually diagnostic but some cases of posterior

cardiac infarction may be difficult to differentiate in the electrocardiogram from acute pulmonary heart disease. The development of localising signs in the lung of pulmonary embolus may help to establish the diagnosis. Other conditions, which must be excluded, are pneumonia, pleurisy, post operative shock and an acute abdominal emergency.

Prognosis—The prognosis after massive pulmonary embolism resulting in acute pulmonary heart disease is extremely unfavourable and death occurs in over 80 per cent of patients. Death is usually delayed for a number of hours or days, but may take place within a few minutes. Smaller emboli seldom cause death, but these are occasionally the precursors of larger emboli, which may prove fatal. In patients who survive a massive pulmonary embolus, the thrombus may undergo organisation and recanalisation.

Treatment—The most important aspect of treatment in massive pulmonary embolus and acute pulmonary heart disease is prophylactic treatment. Unnecessarily prolonged periods of bed rest should be avoided and frequent changes of posture with leg exercises encouraged in chronic bed-ridden patients. In surgical cases, gentle handling at operation of the veins draining the lower extremities and avoidance of tight bandages obstructing the venous return are desirable. Since heart failure seems to predispose to venous thrombosis and pulmonary embolism, energetic and prompt treatment of failure may ward off these complications. If calf vein thrombosis develops and is recognised, a constant watch should be kept for the signs in any chronic bed-patient—two main forms of treatment are available, medical and surgical, in order to help to avoid pulmonary embolism. Anticoagulants may be given in order to prevent extension of the venous thrombus, or in cases where pulmonary embolus has already occurred to prevent growth of the pulmonary embolus by local thrombosis. The principles and details of anticoagulant therapy have already been discussed (see p. 847), and treatment is usually continued for 3 to 4 weeks.

Surgical treatment is by ligation of the femoral or common iliac veins or even of the inferior vena cava. This treatment is usually reserved for cases of recurrent embolism and where anticoagulant treatment is contraindicated.

Treatment of pulmonary embolism itself largely consists of supportive measures to tide the patient over the acute emergency. The patient should be nursed flat in order to encourage cerebral circulation in the presence of a low blood pressure. Oxygen should be given either by B.L.B. mask or in an oxygen tent. Papaverine hydrochloride (0.03 g.) intravenously has been recommended, but it is doubtful if it dilates the pulmonary artery. Venesection is contraindicated, since reduction in systemic venous pressure does nothing to relieve the cause, namely obstruction to right ventricular output. Surgical removal of an embolus from the main pulmonary artery (Trendelenburg operation) can only be carried out if a highly trained team is available and the operation carries a mortality of about 90 per cent.

FAT EMBOLISM

Acute pulmonary heart disease may rarely be caused by fat embolism, resulting from the entrance of fat globules into the systemic veins. The commonest cause of fat embolism is fracture of a long bone, orthopaedic operations, blast injuries and burns may sometimes be responsible. Usually the fat globules are small and obstruct the smaller pulmonary or cerebral arteries. Sometimes however, a large amount of fat may obstruct the main pulmonary artery with the production of acute pulmonary heart disease.

AIR EMBOLISM

The sudden entrance of air in large quantities into the systemic veins often results in death from heart failure. The commonest causes of air embolism are operations

on the neck, diagnostic or therapeutic procedures involving air insufflation, such as tubal insufflation or pneumo-peritoneum. The air entering the right heart, impedes the action of the right ventricle by its compressibility and may block the main pulmonary artery or result in widespread embolism of the pulmonary arteries and arterioles. Death results from acute right heart failure with low cardiac output and anoxæmia.

CHRONIC PULMONARY HEART DISEASE

EMPHYSEMA HEART DISEASE

Ætiology.—Chronic bronchitis is largely a disease of middle-aged men and hence heart disease due to chronic bronchitis and emphysema shows a similar sex and age incidence. The incidence of right heart disease in emphysema is difficult to assess, but it is probable that it occurs in between one-third and one-half of patients.

Pathogenesis.—*Pulmonary hypertension.*—Fixed structural changes in the pulmonary vascular bed, which increase its rigidity or reduce its cross-sectional area, have previously been considered to play the major part in the production of high pulmonary arterial pressure in emphysema. Recently, however, by means of cardiac catheterisation studies, the high resting pressures recorded during cardiac failure have been shown to be transitory and reversible. Permanent structural changes, therefore, cannot alone be responsible for the transient high pressure, although they almost certainly play some rôle in maintaining the moderate pulmonary hypertension seen at rest in patients not in congestive cardiac failure.

Functional factors must therefore be considered in the mechanism of production of pulmonary hypertension in chronic bronchitis and emphysema. It is probable that anoxia is an important factor causing pulmonary hypertension, since the arterial saturation with oxygen is decreased when patients are in congestive cardiac failure and have raised right ventricular pressures, but, with recovery from failure, the saturation returns to a higher level as the pressure falls. The blood volume in emphysema heart disease increases during congestive failure and decreases on recovery and it is possible that this may contribute to the production of transient pulmonary hypertension. Variations in the pulmonary blood flow in emphysema may also influence the height of the pulmonary vascular pressure. The pulmonary arterial pressure rises during exercise as the cardiac output increases, whereas in normal subjects, little alteration in pulmonary arterial pressure results from changes in blood flow. At rest, however, it is unlikely that levels of flow are high enough to be directly responsible for the production of pulmonary hypertension. The extent to which neurogenic activity influences circulation through the pulmonary vascular bed remains uncertain, but there is evidence suggesting that it could play an important rôle.

Cardiac output.—Normal or even increased cardiac output is present in heart failure secondary to lung disease and is one of the features distinguishing it from left ventricular failure (see p. 809). The arteriovenous difference usually remains normal and the cardiac output is therefore appropriate to the raised level of oxygen consumption present in these breathless patients.

Symptoms.—The clinical diagnosis of the onset of cardiac complications in chronic bronchitis and emphysema is a matter of considerable difficulty, since symptoms due to emphysema heart disease are gradually superimposed upon those of pulmonary emphysema.

Three major patterns of onset of pulmonary symptoms are met. There are those who have been subject to repeated episodes of winter colds and "bronchitis" which gradually increase in severity and begin to recur each year. Some date their symptoms from a specific respiratory illness, usually described as "pneumonia". Others

give a long history of asthma with the gradual development of a persistent cough. Regardless of the type of onset the symptoms become similar in all patients with increasing severity of their pulmonary disease and the gradual development of cardiac complications. They have a round the year cough, usually productive of sputum and increasing dyspnoea on exertion. Their exercise tolerance varies considerably; cold weather, fog and minor respiratory infections all increase their dyspnoea, patients subject to asthma however may be most incapacitated in the summer. Owing to interference with the normal oxygenation of the blood they gradually become cyanosed. As the disease progresses recurrent acute exacerbations of bronchitis incapacitate them more until each exacerbation is attended by an attack of severe anoxia and frank congestive cardiac failure. Many patients die within a year of the onset of failure.

Physical signs of pulmonary hypertension may be partly obscured by those of emphysema. Owing to the anatomical changes in the thoracic cage usually associated with emphysema clinical estimation of the cardiac size is usually impossible. For the same reason heart sounds are faint over the præcordium and an accentuated pulmonary second sound is heard only rarely. Forceful pulsation in the epigastrium suggesting right ventricular hypertrophy is often present. By auscultation in the epigastrium it is sometimes easier to detect the triple rhythm of failure than over the præcordium. The presence of a palpable liver should not be considered a sign of venous congestion since most of these patients have a low diaphragm.

The general clinical picture of patients with emphysema heart disease is well known. They have a dusky blue cyanosis and in some cases mild curvature of the finger nails is present. Obvious clubbing usually signifies more pulmonary pathology than mere chronic bronchitis, e.g. bronchiectasis or fibroid changes. Their conversation is often punctuated by laboured breathing. Their thoracic cage is barrel shaped and its movements limited. On auscultation of the chest there may be signs of bronchial obstruction with widespread rales and rhonchi and expiration is always prolonged. In attacks of congestive cardiac failure there is marked cyanosis, the neck veins are distended and there is often considerable œdema. In cases with severe anoxia there may be drowsiness and delirium. Papilloœdema may sometimes be present without localising signs of intracranial disease.

Radiography—Radiography of the chest may show right ventricular and pulmonary artery enlargement in addition to bronchitis and emphysema but are probably not helpful in the early diagnosis of cardiac complications in emphysema. Cardiac enlargement is frequently seen in the presence of congestive cardiac failure.

Electrocardiogram—Similarly the development of cardiographic evidence of right ventricular hypertrophy is often a relatively late event in the clinical course of emphysema heart disease and is seldom of help in diagnosing the inception of the disease. Special points to be looked for are the development of an RSR pattern in right chest leads accompanied by a deep S wave in left chest leads. In some cases tall spiked P waves are seen in standard lead II.

Diagnosis—The diagnosis of emphysema heart disease rests on the recognition of right heart enlargement with or without cardiac failure in the presence of emphysema and bronchitis. The disease is usually difficult to diagnose with certainty until definite evidence of right sided heart failure develops since the symptoms of dyspnoea and cyanosis may be due to respiratory disease alone and since radiological and electrocardiographic evidence of right heart enlargement may be absent in the early stages of the disease. When frank congestive cardiac failure with a rise in jugular venous pressure, hepatomegaly, œdema and triple rhythm have developed the diagnosis is clear. Other causes of right heart enlargement in particular mitral stenosis should be excluded.

Prognosis—Once congestive cardiac failure supervenes the prognosis is poor.

and in spite of treatment, many patients die within a year. The outlook is, however, considerably improved by energetic treatment of attacks of respiratory infection and heart failure.

Treatment—Although no treatment is available to avert the steadily progressive downhill course of emphysema heart disease, much can be done to help the patient in attacks of congestive heart failure. Except where exceptional facilities for complete bed rest and skilled nursing are available at home, admission to hospital is desirable. Episodic pulmonary hypertension in heart failure is often associated with acute exacerbations of bronchitis, and it is probable that acute or subacute respiratory infection plays an important role in the production of pulmonary hypertension. In the treatment of congestive heart failure therefore antibiotics, selected according to the flora in the sputum should always be given. Treatment with bronchodilators (ephedrine or aminophylline) is also useful. Oxygen therapy is of great value in combating hypoxia, but is not without danger, since it may induce carbon dioxide narcosis and should therefore be given intermittently, especially if an oxygen tent is used.

The response to mercurial diuretics during episodes of congestive failure is often excellent. A low salt diet may be helpful. The value of digitalis in the treatment of emphysema heart disease is probably not as great as in other forms of heart failure but there is evidence that it improves myocardial function and it should be tried in all patients.

OTHER CAUSES OF CHRONIC PULMONARY HEART DISEASE—(a) *Fibroid lung*—Widespread pulmonary tuberculosis advanced pneumoconiosis, bronchiectasis, sarcoidosis and scleroderma may all give rise to fibrotic lesions in the lung which if sufficiently widespread may cause chronic pulmonary heart disease.

(b) *Kyphoscoliosis*—Severe kyphoscoliosis is associated in about 75 per cent of cases with chronic pulmonary heart disease, due to concomitant pulmonary emphysema and fibrosis.

(c) *Disease of the pulmonary arteries*—Disease of the pulmonary arteries and arterioles in the absence of disease of the lung parenchyma may sometimes be responsible for chronic pulmonary heart disease. Primary pulmonary arteriolar sclerosis is a rare disease giving rise to pulmonary hypertension and eventually to right heart failure. The pathological lesion is a severe widespread sclerosis of the arterioles. This should not be confused with secondary pulmonary arterial and arteriolar sclerosis, which forms part of the normal ageing process and is a common autopsy finding in patients over the age of 60. In other cases, the lesion is a widespread endarteritis obliterans affecting the pulmonary arterioles, which has been attributed by some to chronic repeated embolisation and by others to syphilis. In other cases there is widespread mural thrombosis extending throughout the pulmonary arterial tree from the main pulmonary artery to the arterioles, which may have resulted from repeated embolisation or from local thrombosis in the pulmonary tree.

These patients often present with substernal pain and faintness on effort. They have signs of pulmonary hypertension, polycythemia, cyanosis and later congestive heart failure. Unlike emphysema heart disease where the history of bronchitis and heart failure is typically episodic, in primary pulmonary hypertension the course is usually steadily downhill. Ethellin and hexamethonium have been given in an attempt to lower the pulmonary arterial pressure but it is doubtful if they influence the course of the disease. Routine treatment should be given for congestive cardiac failure when this supervenes.

Carcinomatous lymphangitis or embolism, causing widespread occlusion of the smaller pulmonary arteries is another rare cause of pulmonary heart disease. The primary neoplasm is commonly a scirrhous carcinoma of the stomach. This form of pulmonary heart disease running a course of a matter of weeks or months has been termed 'acute

Schistosomiasis may also give rise to pulmonary heart disease by recurrent embolism, the schistosome ova becoming impacted in the pulmonary arterioles and giving rise to a granulomatous necrotising arteritis.

SYPHILITIC HEART DISEASE

Syphilis indirectly affects the heart by causing inflammation of the aorta; it is responsible for about 5 per cent. of heart disease in Great Britain, but the incidence is considerably higher in some non-European populations. Syphilitic aortitis is a relatively late manifestation of syphilis but may occur within 5 years of primary infection; clinically it is rarely detected in under 10 years and often not until 30 years after infection. Aortitis occurs in a large proportion of patients with syphilis, treated or otherwise, and in 80 per cent. of patients with neurosyphilis. It is probably present for many years before there are clinical manifestations, and in many patients the disease is discovered for the first time at necropsy.

During recent decades there has been a decline in the incidence of cardio-vascular syphilis, which is probably due to a fall in the incidence of primary infection and more effective early treatment. There is a higher incidence of all forms of the disease in males; for uncomplicated aortitis the ratio of men to women is 3 : 1, but for aortic aneurysm the ratio is 10 : 1. This difference is probably related to physical effort and occupation; similar factors probably explain the higher incidence of complicated aortitis amongst heavy manual workers when compared with sedentary workers. Congenital syphilis rarely affects the cardio-vascular system.

Pathology.—Aortitis is the fundamental lesion in almost all cases of cardio-vascular syphilis; a true spirochætal myocarditis and syphilis of medium-sized vessels are both very rare and they are not considered further.

Syphilitic aortitis begins as an obliterating endarteritis and periarteritis of the vasa vasorum, especially in the ascending aorta; ischæmic changes follow and the media undergoes a slow necrosis with resulting loss of elastic tissue and replacement by fibrosis. The underlying intima is damaged and may ulcerate, but more often it becomes scarred in a characteristic linear fashion. Other areas of the intima undergo thickening from hyalinisation and the development of secondary atheroma with calcification is common. This process of chronic inflammation results in dilatation and irregularity of the aorta which, under the influence of arterial pressure, tends to bulge locally or generally with resultant aneurysm formation. Saccular aneurysms may occur in more than one place and they are often filled with layers of partially organised clot. Surrounding structures are frequently damaged by pressure and adjacent bone is eroded.

The ascending aorta suffers most and aortitis usually extends down to the level of the aortic valve ring, causing dilatation at the aortic base; this is the most important factor in the production of aortic incompetence. The valve cusps contribute to the incompetence through a valvulitis which is shown by a thickening of the free upper edges and by a bulbous intimal thickening of the commissures.

If the mouths of the coronary arteries are situated above or near the upper margin of the sinus of Valsalva, they tend to be taken up in the aortitis and partially closed. Ischæmic changes of the myocardium follow and histologically a widespread diffuse fibrosis is not uncommon, such changes have been confused with syphilitic myocarditis, which is extremely rare. Gummata in the heart are also very rare but localised lesions in the ventricular septum are occasionally the cause of heart block.

Clinical Features.—The clinical features of syphilitic aortitis are due to aneurysm formation, or to basal aortitis, which causes coronary ostial stenosis and aortic incompetence.

Uncomplicated syphilitic aortitis presents no diagnostic symptoms, but a dull aching substernal pain which is constant and localised has occasionally been described. In patients known to have latent syphilis a loud second sound over the aorta or an aortic systolic murmur in the absence of hypertension suggests the possibility of aortitis. Radiological examination should be carried out in all cases of late syphilis and widening or irregularity of the aorta may be discovered before the clinical features of aortitis have developed.

Angina pectoris commonly develops in syphilitic aortitis. It is due to stenosis at the origins of the coronary arteries and is mostly accompanied by incompetence of the aortic valves which are also damaged by the aortitis. Coronary ostial stenosis produces cardiac pain on effort which is indistinguishable from angina pectoris due to coronary atheroma. However, syphilitic cardiac pain tends to last longer and often comes on at rest, especially at night; it is not readily relieved by trinitrin and a dull, substernal ache tends to persist between the attacks. Coronary ostial stenosis occasionally causes acute coronary insufficiency, but massive cardiac infarction is rare. As in all conditions producing cardiac ischæmia, sudden death is not uncommon.

Aortic incompetence is due to dilatation of the valve ring, thickening of the cusp margins, and thickening of the commissures by fibrotic granulation tissue. It is more common in males than in females, in the ratio of 3 to 1. There are no symptoms until pathological dyspnœa indicates early heart failure or cardiac pain indicates involvement of the coronary ostia.

The physical signs are as in rheumatic aortic incompetence (see p. 874). A mid-systolic murmur is usually present in addition to the early diastolic murmur and both are heard best at the "aortic area" or in the left parasternal region. The systolic murmur, though similar to that found in aortic stenosis, is not loud enough to cause a thrill and does not indicate stenosis. The incompetence soon becomes well established with gross signs in the peripheral vessels and the murmur takes on a "to and fro" character. There are no accompanying signs of mitral valve disease, but when the leak is severe a functional presystolic murmur may develop (Austin Flint murmur); this is thought to be due to the large aortic regurgitant stream preventing complete opening of the anterior mitral valve cusp. The apex becomes heaving and characteristic of left ventricular hypertrophy.

Left ventricular failure, as shown by effort dyspnœa or cardiac asthma, appears early in the disease, and thereafter deterioration is relatively rapid, especially when cardiac pain indicating myocardial ischæmia is also present.

Aneurysms of the aorta.—Diffuse fusiform dilatation and localised saccular bulging of the aorta are common in syphilitic aortitis. Radiological examination is essential to the diagnosis of both conditions but a saccular aneurysm often produces characteristic symptoms and signs which depend on its anatomical site. Some aneurysms remain symptomless for many years, but others cause severe pressure pain, and rupture may occur after a relatively short period.

Aneurysm of the ascending aorta.—Aneurysm in this situation may present a local bulge in the anterior chest wall, usually to the right of the sternum. Those skilled in percussion may detect dullness to the right of the sternum before superficial bulging occurs. The second sound due to aortic valve closure is often sonorous and usually heard widely in the right chest and often in the right axilla. A dull sternal pain due to rib erosion is common, but many aneurysms are symptomless for a long time. Aortic incompetence and angina pectoris tend to develop with aneurysms in this situation. Sometimes the right bronchus is compressed with the development of partial atelectasis, and occasionally a medial extension of the aneurysm leads to deviation of the trachea. Death may be due to external rupture of the aneurysm, or more commonly to rupture into the pleura, pericardium or bronchus.

Aneurysm of the arch of the aorta produces symptoms and signs by pressure on adjacent structures in the superior mediastinum. The orifices of vessels arising from the aorta are frequently involved and cause differences in the pulse pressures in the two arms. Compression of the great veins leads to a pulseless distension of the veins of the neck and upper chest wall. The bloated facies of superior mediastinal obstruction are characteristic. Pressure on the trachea produces stridor and an unproductive cough, whilst damage to the recurrent laryngeal nerve causes changes in the voice and cough. Hæmoptysis may be due to congestion of the tracheal mucosa, or a leak from the aneurysm which not uncommonly ruptures into the trachea. A tracheal "tug" may be detected with each heart beat by placing the tip of a finger under the cricoid ring. Upward and backward extension of an aneurysm into the paravertebral sulcus may lead to severe brachial neuralgia and a Horner's syndrome from sympathetic paresis. The phrenic nerve is sometimes damaged with resulting paralysis of the diaphragm. Death from rupture of the aneurysm into trachea, pleura, mediastinum or pericardium is usual.

Aneurysms of the descending aorta may develop to a large size without producing symptoms. They almost never occur below the origo of the celiac vessels and rarely below the diaphragm. Erosion of vertebrae may cause a severe constant pain in the back and occasionally large aneurysms present in the posterior chest wall. Aneurysms in the abdominal aorta are usually symptomless but may be palpated in the epigastrium; they rarely cause pressure symptoms on

postero-anterior and oblique views, together with radioscopy, should be carried out in all cases of late syphilis, treated or otherwise

The electrocardiogram in syphilitic aortitis may be normal if the lesion is uncomplicated, or pathological when there is ischæmia from coronary ostial stenosis or ventricular hypertrophy from aortic incompetence. When cardiac pain indicates ischæmia the electrocardiogram usually shows varying degrees of S-T depression and inversion of T waves in lead I and left-sided chest leads. The changes are similar to those found in ischæmic heart disease due to coronary atheroma and emphasise the frequent occurrence and severity of ischæmia in syphilitic aortitis. Pathological Q waves from massive infarction do not occur.

Serological tests are positive in some 80 per cent of patients with syphilitic aortitis (see p 211). Past treatment often modifies these tests without having influenced the development of aortitis. In some cases blood reactions are negative whilst the cerebrospinal fluid may show a positive reaction. The erythrocyte sedimentation rate is frequently raised and is related to the degree of activity of syphilitic aortitis in some cases.

Diagnosis.—Isolated aortic incompetence in an adult over 30 years of age is possibly due to syphilis, if the leak is great and rapidly developing syphilis is a probability, and if it is associated with cardiac pain, it is almost a certainty. The association of aortic incompetence with signs of neurosyphilis or positive serological reactions confirm the diagnosis of syphilitic aortitis. Radiological examination is the most important aid to diagnosis, and should be carried out in all suspected cases, dilatation of the aorta, irregularity of its calibre and calcification in the wall of the ascending portion are diagnostic points, but should not be confused with the smooth aortic unfolding and tortuosity which occur with hypertension and with atherosclerosis in the elderly.

The differential diagnosis of aortitis from cardiac pain due to coronary atheroma is not difficult because in syphilis there is usually an associated aortic incompetence. The early diastolic murmur should be carefully sought. Rheumatic aortic incompetence presents difficulties in differential diagnosis when it occurs alone, but often there is associated aortic stenosis or mitral valve disease, rheumatic aortic incompetence is usually less severe and there is often a history of rheumatic fever, and on radiological examination the aorta is not dilated or calcified although the aortic valves are usually calcified when there is aortic stenosis.

The diagnosis of aortic aneurysm is essentially radiological unless the aneurysm presents as a pulsating superficial swelling. Aneurysm should be suspected when there are signs of superior mediastinal obstruction with cough, a pathological aortic second sound, differences in the pulses of the arms and other signs of syphilis. The differential diagnosis from mediastinal tumours and bronchial carcinoma is sometimes difficult, angiocardiology is confirmatory when simpler methods are inadequate.

Positive serological tests are strong evidence that the clinical findings in question are due to syphilis, but this is not always so, conversely, in aortitis, tests do not exclude syphilis, for in some 15 to 20 per cent of cases they are negative.

Prognosis.—The history of patients with syphilitic aortitis is extremely variable. Some pursue a rapid, downhill course whilst others live long and die of another malady. Consequently prognosis is difficult. In aortic insufficiency there is often a long, asymptomatic period, and after the appearance of symptoms many patients live from 5 to 10 years, but few patients live more than 2 years after definite signs of heart failure have appeared. Cardiac pain indicating coronary ostial stenosis is an adverse factor in all cases and sudden death is not uncommon. The prognosis for cases of aortic aneurysm is also variable. Some appear to progress rapidly whilst in others the condition appears to be stationary, and many live for more than 10 years. Heavy physical work is an unfavourable factor and probably women do better.

than men. Antisyphilitic treatment carried out in the asymptomatic stages appears considerably to improve the outlook, but it is doubtful whether treatment has much influence in the later stages of the disease.

Treatment.—The management and treatment of syphilitic heart disease consists of the treatment of syphilis and of the sequelæ of aortitis.

All untreated cases of syphilitic heart disease should receive a course of anti-luetic treatment after the cerebrospinal fluid has been examined. The course of advanced disease is probably not materially altered by this treatment, but the prognosis of uncomplicated and mild cases is improved since there is active syphilitic inflammation in all untreated cases.

The risks of treatment are slight, but an acute exudative reaction (Jarisch-Herxheimer reaction) accompanied by fever may occur within 24 to 48 hours. In patients with coronary ostial stenosis this may be serious and lead to acute coronary insufficiency. Rarely contracting scar tissue may result in the therapeutic paradox of increased aortic incompetence or increased cardiac pain. In general there is no element of urgency in treatment of the luetic condition, so that a course of bismuth or iodides, which diminish the risk of severe reactions from the more powerful anti-luetic drugs, should be given first. Various schedules of treatment are recommended and may be modified to suit individual cases (see also general article on syphilis, pp. 212, 221). The following method is satisfactory for most cases of syphilitic heart disease. A single weekly injection of metallic bismuth (0.3 g.) is given together with potassium iodide (gr. 10 t.d.s.) for 4 weeks, then a daily injection of procaine penicillin (600,000 units) is given for 12 days, making a total of 7.2 million units. Bed rest is advisable for the first week or so and again during treatment with penicillin. Six further weekly injections of bismuth (0.3 g.) complete the course. After 6 months the Wassermann reaction, sedimentation rate and the general condition of the patient should be reviewed; if there is any evidence of activity or deterioration a modified course of anti-luetic treatment should be repeated, and thereafter the situation should be reviewed at regular intervals.

Cardiac pain should be treated as described (see p. 840), but the nitrite drugs are not as effective as in angina pectoris due to coronary atheroma.

Heart failure in aortitis should be treated as in other cases of left ventricular failure (see p. 812). A prophylactic low salt régime is advisable as soon as effort dyspnoea is present.

TREATMENT OF AORTIC ANEURYSM.—Pain may necessitate the frequent use of analgesic drugs. Various operative procedures have been devised to treat aneurysms of the aorta, but none have had great success. Wires introduced into the aneurysm were thought to limit extension by causing clot formation. Cellophane wrapped around the aneurysm induces a fibrous tissue reaction which may limit further extension and strengthen the wall. Excision of the aneurysm has been performed but the pathological state of the remaining aorta is not conducive to effective reconstruction and grafting.

CHRONIC VALVULAR DISEASE

MITRAL VALVE DISEASE

Chronic mitral valvulitis is the commonest form of rheumatic heart disease. The valve may be narrow, thereby offering an obstruction to the circulation (mitral stenosis) or it may be incompetent. Dominant mitral stenosis with some lesser degree of incompetence is the commonest form of organic mitral valve disease, but all grades of the combination occur and either lesion may occur alone, pure mitral stenosis being much commoner than pure mitral incompetence.

Ætiology.—Mitral stenosis is almost always due to rheumatic heart disease

although only some 60 per cent of adult patients give a history of rheumatic fever. In the majority of patients with acute rheumatic carditis the mitral valve is involved and it is affected in some 85 per cent of cases of chronic rheumatic heart disease examined at necropsy. During the first attack of acute rheumatic carditis, mitral valvulitis causes incompetence but this is a transitory lesion and many patients ultimately develop stenosis. Mitral stenosis is more common in females in the ratio of 3:1. Pure organic mitral incompetence in adults is relatively rare and is probably due to rheumatism in most cases, but only 25 per cent give a past history of rheumatic fever, mitral incompetence also differs from pure mitral stenosis in the sex incidence since men are affected rather more commonly than women.

Functional mitral incompetence is common, it develops when ventricular dilatation from any cause results in dilatation of the valve ring and stretching of the chordæ tendinæ and papillary muscles. Bacterial endocarditis may cause ulceration of mitral valve cusps or rupture of chordæ tendinæ producing acute mitral incompetence or an increase of pre-existing incompetence. Occasionally fracture of chordæ tendinæ may occur at the junction with papillary muscles as a result of cardiac infarction. Congenital lesions of the mitral valve are rare but a few cases of congenital mitral stenosis have been reported.

Pathology.—In chronic rheumatic mitral valvulitis the valve cusps are thickened and deformed to varying degrees. The chordæ are also shortened and thickened by fibrosis. In stenosis the orifice of the valve is narrowed by fusion of the cusp margins whilst rigidity and thickening of the cusps and chordæ holds the valve in a relatively fixed position so that a narrow slit is formed. The whole ring, cusps and chordæ may be fused into a narrow rigid funnel. Incompetence results from deformity of the cusps, and from shortening and sclerosis of the chordæ. In pure incompetence the valve ring is thickened and immobile and the chordæ are shortened, but there is no fusion of the commissures. Calcification in the valve ring and adjacent cusps is not uncommon. Microscopic examination shows vascularisation of the cusps and thickening from fibrosis.

The left auricle is dilated and its walls are thickened in mitral stenosis and incompetence. The mural endocardium is often scarred and a thickened patch is especially likely to occur above and adjacent to the valve ring when there is incompetence. The lumen of the auricular appendage is sometimes obliterated by clot and layers of partially organised clot may line the auricular chamber. In mitral stenosis the left ventricle tends to be small (except when there are aortic valve lesions or systemic hypertension), whereas in mitral incompetence the left ventricle is dilated and moderately hypertrophied. In mitral stenosis the right ventricle is hypertrophied and dilated to varying degrees. The lungs are especially damaged in mitral stenosis, they become brownish, indurated and inelastic, the small branches of the pulmonary artery are thickened and project from the cut surface of the lung. Pulmonary infarcts of varying size are common. On microscopic examination the alveolar walls are thickened, the capillaries dilated and the alveolar cavities tend to contain cellular debris and large "heart failure" cells containing iron pigment.

MITRAL INCOMPETENCE

In mitral incompetence the left auricle receives a regurgitant stream of blood during ventricular systole, in addition to the inflow from the pulmonary veins. The auricular pressure rises with ventricular systole, but the absence of obstruction at the mural orifice prevents the development of diastolic hypertension in the auricle. The left ventricle is overfilled in diastole by the augmented volume, and an effective output into the aorta is maintained by rapid ejection. The increased stroke volume is expelled at relatively normal pressures and compensation is thus maintained by the left ventricle at the expense of only a slight increase in cardiac work.

Pressures do not rise greatly above normal in the left heart except for a systolic peak in the auricle so that pulmonary congestion and pulmonary hypertension are not prominent features. The hypervolaemic state of the left heart is well tolerated if the muscle is good, hypertrophy is not great, and heart failure tends to develop late in the disease.

Symptoms—There are no symptoms peculiar to mitral incompetence. The pure lesion is well tolerated and many patients remain in active employment to the sixth or seventh decade. Palpitation due to extrasystoles is common. Some patients complain of fatigue and weakness rather than breathlessness, which tends to appear late. Many die of an intercurrent disease. Patients with severe mitral incompetence develop heart failure which does not respond well to treatment and when rupture of the chordæ causes acute mitral incompetence, severe heart failure tends to occur.

Signs—The pulse is normal or full and rapidly rising—almost waterhammer in some patients. In cases where regurgitation is considerable, ventricular overfilling may be appreciated at the apex which is hyperdynamic, after the lift of systole, which is never as forceful as in left ventricular hypertension. A small diastolic filling wave may be seen or palpated. Many patients have minor degrees of incompetence which do not alter the pulse or apex beat, and a systolic murmur is then the only sign.

Auscultation provides the most significant signs of mitral regurgitation. The first sound is normal and it is immediately followed by a systolic murmur which is loudest at the apex and radiates towards the axilla, very loud murmurs may be palpated as an apical systolic thrill and are widely heard in proportion to their loudness. The murmur is pansystolic and tends to be crescendo in late systole, occasionally the murmur appears to be confined to late systole but phonocardiograms show that vibrations start early in systole. The second sound is often inaudible at the apex, being buried in the murmur. A third heart sound, related to augmented ventricular filling is frequently present. In pure cases the first heart sound is not loud, there is no opening snap and no mid diastolic murmur and usually no signs of pulmonary hypertension. Extrasystoles are common, and auricular fibrillation may occur late in the disease.

Radiology—Radioscopy shows a varying degree of left auricular enlargement, but the most important change is in the dynamics of the auricle which may be seen to expand during ventricular systole. In the anterior view the left auricle expands laterally in systole appearing as a momentary bulge high up on the left border and as a less obvious bulge in the upper part of the right border. In the oblique views the barium filled oesophagus is moved backwards by the left auricle during ventricular systole. Systolic expansion indicates a considerable degree of mitral regurgitation and the absence of this sign does not mean that there is no regurgitation. Slight to moderate enlargement of the left ventricle is also seen.

The electrocardiogram may show the presence of arrhythmia. The standard leads tend to show normal or left axis deviation. Left sided chest leads may show the signs of slight to moderate left ventricular hypertrophy.

Complications—Bacterial endocarditis may occur on the scarred valve in mitral incompetence and it is not an uncommon complication in mild cases when a mitral systolic murmur is the only evidence of abnormality.

Diagnosis—Mitral incompetence should not be diagnosed lightly on the finding of a systolic murmur. A pansystolic murmur which is loudest at the apex and engulfs the second sound there is highly suggestive of organic mitral incompetence in the absence of any cause for cardiac dilatation. A hyperdynamic apex beat is further evidence. Expansion of the left auricle in ventricular systole seen on radioscopy is confirmatory. The diagnosis of mitral incompetence in dominant mitral stenosis is suggested by the presence of an apical pansystolic murmur in addition to the signs of mitral stenosis. Furthermore, mitral incompetence in this combination is frequently

associated with calcification of the mitral valve seen on screening. The sudden appearance of a pansystolic murmur at the apex during the course of cardiac infarction or bacterial endocarditis suggests acute mitral incompetence due to the fracture of chordæ tendineæ.

The murmur of ventricular septal defect is also pansystolic (a separate mid-systolic murmur may be heard over the pulmonary artery) and may be heard easily at the mitral area, but is loudest near the sternum. A functional mid-diastolic murmur may be present in ventricular septal defect and adds to the difficulty of differentiation from mitral valve disease, but on radiography there is pulmonary plethora without left auricular enlargement.

Other conditions causing a systolic murmur at the apex must be differentiated. Innocent murmurs are soft and most are parasternal or over the pulmonary artery. At the apex a very short late systolic murmur may be innocent, but such a murmur is readily confused with the late systolic crescendo murmurs of mitral disease. However, it should be fully understood that when such a murmur is the only indication of mitral disease (i.e. when there is no cardiac enlargement) the prognosis is good, the patient should live a normal life and be reassured, and the only added risk is the remote possibility of bacterial endocarditis.

Mid systolic murmurs arise from ejection and flow into the great vessels. The murmur of aortic stenosis may be loud at the mitral area, but the second sound is audible and the murmur is also heard at the aortic area, and the pulse is characteristic. Anæmia, thyrotoxicosis, pregnancy, kyphoscoliosis and sternal depression may also produce mid systolic murmurs, but these are usually soft, loudest in the parasternal region and the cause is usually obvious.

Prognosis—The prognosis of functional mitral incompetence depends on the cause of cardiac dilatation. In acute rheumatic carditis mitral incompetence is a product of valvulitis and cardiac dilatation, immediate prognosis depends on the severity of the rheumatic process and the remote prognosis is variable, a few recover completely, many develop mitral stenosis and a few are left with organic incompetence only. In established organic mitral incompetence the prognosis is excellent in mild cases and a normal life span can be expected. In moderate cases with enlargement, heart failure may supervene after middle life, and this tends to be fairly rapidly progressive. Heart failure responds indifferently to the usual treatment and death occurs in a year or so of the onset of failure. Bacterial endocarditis may occur in any patient with mitral incompetence, whether the lesion is mild or severe. Early treatment may cure, but further deterioration is likely if treatment is delayed or ineffective, fracture of chordæ tendineæ causing a greater degree of mitral incompetence is common. Embolism and auricular fibrillation are much less common in mitral incompetence than in mitral stenosis.

Treatment—The great majority of patients with organic mitral incompetence have only slight symptoms or none at all, they require no treatment and they should be reassured. However, it is advisable to give these patients a prophylactic injection of penicillin before undergoing dental extraction or other operation in a septic field. Heart failure is treated by routine methods.

In patients with severe organic mitral incompetence causing heart failure, surgical repair of the valve has been attempted, various methods are under investigation but none is yet satisfactory.

MITRAL STENOSIS

The essential feature of mitral stenosis is obstruction to blood flow through the valve orifice during diastole. Symptoms are not produced until the area of the orifice is reduced from normal (8.5 sq cm) to approximately 2.5 sq cm, although the signs are present with lesser degree of stenosis. Increasing hæmodynamic disorder

and a resulting increase in severity of symptoms occurs with greater degrees of stenosis, and most patients are bed-ridden when the valve orifice is less than 1 sq cm

In significant mitral stenosis the blood flow to the left ventricle is diminished and the pressure and volume of blood in the left auricle rises. The high auricular pressure and increased contraction of the auricle, which shows compensatory hypertrophy, result in an increased pressure gradient across the valve which partially compensates for the obstruction. The increased left auricular pressure is transmitted to pulmonary veins, pulmonary capillaries and the pulmonary artery. Some degree of pulmonary hypertension develops in the majority of patients with severe mitral stenosis, and in some the pressure rises to very high levels from a greatly increased pulmonary vascular resistance, which appears to be due to arteriolar spasm and secondary changes in the vessel walls. Pulmonary hypertension causes right ventricular hypertension and compensatory hypertrophy.

Compensation occurs at the expense of muscular hypertrophy and increased work of the left auricle and right ventricle. Decompensation may occur in the left auricle for its walls are relatively thin, it is also affected by rheumatism and auricular fibrillation is common, this produces the syndrome of left heart failure. Decompensation of the right ventricle produces the features of right heart failure. The raised tension and congestion throughout the pulmonary circulation causes severe secondary changes in the lungs.

Clinical Features—Patients with mild mitral stenosis are asymptomatic and may remain so throughout a long life, but this is unusual. Sooner or later most patients with mitral stenosis develop symptoms of left heart failure, and ultimately congestive heart failure.

Dyspnoea—Breathlessness on effort tends to occur during early adult life in most cases of mitral stenosis. Effort tolerance steadily diminishes unless episodes of pulmonary infarction, pulmonary oedema, auricular fibrillation or bronchitis cause relatively rapid phases of deterioration. Sudden paroxysmal attacks of cardiac asthma are not uncommon and may even appear in apparently mild cases before effort dyspnoea is noticed, cardiac asthma may occur during the day, but is more common at night and often occurs for the first time during pregnancy, some attacks are more severe and reach the stage of pulmonary oedema. Pulmonary oedema tends to occur in those patients with slight or only moderate pulmonary hypertension rather than in those with very high levels of pressure, it is characterised by extreme respiratory distress, expectoration of pink frothy sputum, cyanosis, hypotension and peripheral vasoconstriction. The various forms of dyspnoea due to left auricular failure tend to subside when right heart failure develops.

Right heart failure—The signs of congestive cardiac failure may develop slowly or appear rapidly after a variable period during which dyspnoea has been the dominant symptom. Oedema appears at the ankles, the jugular venous pressure is raised, and the liver becomes palpable and tender. In some patients this phase brings relief from the symptoms of pulmonary congestion, but in many it does not. During the early stages of right heart failure, discomfort and even pain in the right hypochondrium and epigastrium may accompany effort and are due to hepatic congestion. Right heart failure steadily increases, but with treatment improvement occurs and many episodes may recur before a chronic unresponsive stage is reached, which is characterised by a low fixed cardiac output. Activity is then severely restricted by dyspnoea and fatigue, appetite is poor and weight loss is evident, tricuspid incompetence is often gross but saves the patient from paroxysmal dyspnoea, the liver becomes large, firm and pulsatile, and recurrent ascites may be a serious problem. Slight icterus from cardiac cirrhosis is usually present.

Hæmoptysis is a common symptom at various stages of the natural history of mitral stenosis. There are three main types: pink staining of the sputum with relatively small quantities of blood due to pulmonary congestion, occasional massive

hæmoptysis, and blood-stained sputum associated with pleural pain which indicates the presence of pulmonary infarction. Hæmoptysis may be repeated many times over a span of years.

Pain in the chest in mitral stenosis is not a prominent feature, but there are three types: a submammary discomfort which is probably psychogenic and reflects anxiety about the heart condition; a dull præcordial discomfort when there is great cardiac enlargement, and true ischaemic cardiac pain which is due to failure of the coronary circulation when there is a low cardiac output, pulmonary hypertension and anoxæmia. Most patients, however, do not complain of pain.

Dysphagia, a dry persistent cough, or hoarseness of the voice may occur from pressure on adjacent mediastinal structures by an enlarged left auricle. Very rarely aneurysmal enlargement of the left auricle appears to be the cause of erosion of the vertebral bodies giving rise to severe pain between the scapulae.

Signs.—Mitral stenosis presents a pattern of characteristic signs, some of which are directly related to the valve lesion and others to the secondary hæmodynamic disturbance. The most constant and important one is the apical diastolic murmur set up during the passage of blood through the obstruction.

There is often a slight bulging in the left præcordium, the cardiac impulse may be seen in the parasternal intercostal spaces (right ventricle) and the apex beat (left ventricle) is seen as a separate pulsation farther to the left. On palpation the apex beat is localised and it has a sharp, tapping quality, largely due to vibrations of the loud first heart sound. An apical diastolic or presystolic thrill is common and its presence depends on the loudness of the characteristic murmur. Over the parasternal region there may be a strong pulsation due to right ventricular hypertrophy, indicating pulmonary hypertension, which is also suggested by a palpable second sound over the pulmonary artery.

On auscultation the first sound is mostly sharp and loud; it can be heard over the whole præcordium but is loudest at the apex. A soft systolic murmur is common at the apex but in pure mitral stenosis systole may be significantly silent. The second heart sound is loud at the pulmonary area and its second component due to pulmonary valve closure is especially loud when there is pulmonary hypertension. An additional sound, the "opening snap", occurs shortly after the second heart sound, which it resembles in pitch and brevity, but it is loudest just internal to the apex. The "opening snap" is audible in most cases of mitral stenosis but, like the first heart sound, it is soft when there is gross calcification of the mitral valve. The opening snap is distinguished from the second component of a widely split second sound by timing and by the area where they are best heard: the third heart sound is distinguished by its low-pitched quality, but this sound does not occur in dominant mitral stenosis. The "opening snap" appears to be essentially related to the pathological state of the valve itself.

A low-pitched, rumbling, mid-diastolic murmur follows the opening snap. This murmur is best heard through a bell stethoscope placed lightly on the apex, with the patient reclining and slightly tilted to the left side. The mid-diastolic murmur may be short in mild cases, but it is mostly long and continues throughout diastole. When the rhythm is normal, the diastolic murmur merges into a sharp, crescendo murmur—the presystolic or auricular systolic murmur, which is most readily heard after brief exercise. When there is severe pulmonary hypertension, auricular fibrillation and a very low cardiac output, there may be no murmurs and the opening snap may be the only sign to indicate the diagnosis.

The arterial pulse tends to be small in mitral stenosis and the blood pressure is often low, but in some patients mitral stenosis is associated with systemic hypertension. The venous pulse may show prominent "a" waves when there is pulmonary hypertension and the rhythm has remained regular. A general rise in the level of venous pressure occurs when there is right heart failure.

Auricular fibrillation occurs in the great majority of patients with mitral stenosis. Its onset marks a definite stage of deterioration and it is responsible for further diminution of cardiac reserve. A phase of changeable rhythm when auricular ectopic beats are frequent or short periods of auricular fibrillation alternate with normal rhythm often precedes the establishment of permanent auricular fibrillation. The change to abnormal rhythm may be associated with symptoms of palpitation, increased dyspnoea and fatigue, and sometimes congestive cardiac failure first appears at this time. Auricular fibrillation is usually responsible for tachycardia, but when the heart is very large there is often a high degree of block, causing a slow heart rate.

MITRAL STENOSIS AND INCOMPETENCE—The signs of the common combined lesion depend on the relative dominance of regurgitation or obstruction. The signs of mitral stenosis are modified by additional incompetence, as follows. The apex tends to be less localised, the tapping quality is less obvious and it tends to become more hyperdynamic and left ventricular in character. The signs of pulmonary hypertension may or may not be present. The first sound and the opening snap are softer when there is calcification of the mitral valve, which is commonly associated with a mixed lesion. A pansystolic murmur is usually present—the absence of an apical systolic murmur means there is no significant incompetence. When mitral incompetence is great the opening snap is replaced by a third heart sound.

Radiology—Asymptomatic patients with mild mitral stenosis show no abnormal features apart from slight backward bulging of the left auricle in the right oblique view. In all of the more severe degrees of mitral stenosis the enlarged left auricle may be seen as a hump below the pulmonary arc and as a bulge below the right hilum, and when penetrating films are taken the contour of the whole auricle may be seen through the heart shadow. The barium filled oesophagus is deviated backwards in a characteristic curve, usually best seen in the right oblique view, but in some patients the oesophagus is deviated to the left and left oblique views then show the large left auricle surmounting a small left ventricle. The left auricle may be aneurysmal and seen bulging across the right hemithorax almost to its lateral wall. In advanced cases the right auricle is also large. The aorta tends to be small and the pulmonary artery tends to be large. The heart shadow develops a rather triangular shape.

The lungs show varying degrees of congestion. The hilar shadows are large and the clear outlines of vessels are often blurred. The peripheral lung fields lose normal translucency, show a fine reticulation and occasionally large miliary shadows due to hæmorrhoidosis are seen. Wedge shadows of pulmonary infarcts are common and small effusions frequent. The lung parenchyma in the costophrenic angle shows horizontal thread-like lines in cases of long standing congestion.

The electrocardiogram—P waves are characteristically widened and notched especially in lead II and left sided chest leads. The second peak of the notch is due to delayed left auricular activation. The P waves may be single and tall when there is severe right heart hypertension. The QRS complex shows varying degrees of right axis deviation in cases with pulmonary hypertension. The chest leads show increased positivity on the right side depending on the degree of right ventricular hypertrophy.

Complications.—Hæmoptysis, cardiac asthma, pulmonary oedema and pulmonary infarction are sufficiently common to be considered a part of the natural history of the disease. The most important complications are due to peripheral emboli arising from clot in the left auricle. Embolisation may occur in patients with mild mitral stenosis and normal rhythm, but patients having auricular fibrillation are more commonly affected. Emboli are of varying size. Medium sized cerebral and limb vessels are frequently occluded, aphasia with hemiplegia is a common sequel to middle cerebral arterial embolism and may be transient or permanent. Renal infarction, splenic infarction and mesenteric infarction sometimes occur. Many patients have repeated attacks of arterial occlusion. A massive clot may even occlude the aorta at its bifurcation with resulting severe pain in the legs, buttocks and abdomen.

and peripheral signs of arterial insufficiency. Occasionally massive clot in the left auricle may become free and occlude the narrow mitral orifice causing sudden death. Rarely recurrent attacks of syncope, characteristically relieved by a change of position, are due to intermittent occlusion of the mitral orifice by a ball valve thrombus. Bacterial endocarditis is a very rare complication of pure mitral stenosis.

Diagnosis.—The diagnosis of stenosis of the mitral valve depends on the findings on auscultation and radiology. A loud and sharp first heart sound, usually palpable, is strongly suggestive, but a low-pitched mid-diastolic murmur at or near the apex is the essential evidence of mitral stenosis; the opening snap is further evidence when there is doubt about the presence of a mid-diastolic murmur. Rarely, when the flow through the valve is greatly reduced, the mid-diastolic murmur may become inaudible and then the opening snap and sharp first heart sound are the only auscultatory signs. Left auricular enlargement determined by radioscopy confirms the clinical diagnosis and in conditions where a mid-diastolic murmur may be functional (as in ventricular septal defect), the presence or absence of left auricular enlargement is decisive.

The diagnosis of mitral stenosis is incomplete without an assessment of the functional state of the circulation. Particular attention should be paid to effort intolerance, paroxysmal dyspnoea, hæmoptysis, embolisation, rhythm, the signs of pulmonary and systemic congestion, and the presence and approximate level of pulmonary hypertension which is recognised by the degree of right ventricular hypertrophy and the loudness of the pulmonary second sound. Difficulties in the assessment of the state of the pulmonary circulation are likely to arise in some patients when mitral stenosis is combined with mitral incompetence or with pulmonary disease; in such cases the pulmonary artery pressure, pulmonary capillary pressure and the pulse pressure tracings should be obtained by cardiac catheterisation. Diagnosis in mitral stenosis must include an assessment of the state of other valves which are often affected.

Differential diagnosis of the signs: on casual auscultation a normal split first heart sound may be mistaken for a presystolic murmur, but in mitral stenosis the mid-diastolic murmur, loud first sound and opening snap, as well as the radiological signs are present. In pure aortic incompetence a presystolic murmur (Austin Flint) may be present, but the other signs of mitral stenosis are absent and the aortic lesion is always severe. Functional diastolic murmurs also occur in auricular septal defect and ventricular septal defect, but in these conditions also attention to the detailed findings of auscultation show that the other signs of mitral stenosis are absent, whilst the signs of a left to right shunt are present on clinical examination and on radiography.

Differential diagnosis of symptoms: hæmoptysis and dyspnoea may suggest pulmonary disease, paroxysmal dyspnoea may suggest left ventricular disease or bronchial asthma and embolisation may cause symptoms referable to any organ, but when the physical signs of the mitral valve lesion are recognised the ætiology of these symptoms is usually clear.

Course and Prognosis.—A minority of patients live a normal life span and a minority deteriorate progressively from attacks of rheumatic fever in childhood and adolescence. Most die of the disease between the ages of 30 and 50, the average age at death being 35; most of these have had a symptom-free period in early adult life, followed by the development of increasing effort dyspnoea and then congestive heart failure. The prognosis in an individual case depends on a full assessment of many factors; the presence of recurrent rheumatic activity, severe pulmonary hypertension and right heart failure are serious adverse factors. Patients with auricular fibrillation may live for several years but many die within 3 years of its onset and peripheral embolism is, at any time, an additional hazard. Pregnancy is tolerated moderately well, but it is noticeable that many patients have their first symptoms or a first attack of heart failure at this time. Favourable factors in prognosis are a continued absence

of symptoms in the third decade, absence of rheumatism, a small heart with no signs of pulmonary hypertension on clinical examination and the absence of right ventricular preponderance on the electrocardiogram. A short and soft mid diastolic murmur with a normal pulse volume, together with the factors mentioned, suggests that the valve has an area greater than 2 sq cm and that the obstruction is slight and prognosis correspondingly good. Successful mitral valvotomy reverses much of the symptomatology, diminishes pulmonary hypertension and may restore some patients to a relatively normal life, but sufficient time has not passed to appraise the long term results of this operation.

Treatment—Asymptomatic patients with mild mitral stenosis having no evidence of pulmonary congestion or pulmonary hypertension do not require treatment. All other patients with dominant mitral stenosis must be considered as possible subjects for mitral valve surgery unless the severity of the disease and great enlargement of the heart are obvious contraindications. Surgery offers the only cure of the disease.

General—Exercise in patients without heart failure should not be unduly restricted but it should be kept within the limits imposed by symptoms. Occupation though largely dictated by economic and social factors should be regular and not of the manual variety. In pregnancy there should be regular frequent medical supervision and regular hours of extra daily rest. A period of 2 weeks partial bed rest is advisable before delivery, which is best conducted in hospital or similar institution. Mitral valvotomy should be performed during pregnancy if symptoms are severe and increasing in severity.

The symptoms of mitral stenosis are largely due to heart failure which should be treated by routine methods (see p 812 *et seq*). Digitalis may be given at any stage, whether rhythm is regular or not, preferably early rather than late in the natural history of the disease. Sodium restriction is advisable in co operative patients and may prevent attacks of pulmonary oedema, mercurial diuretics are necessary at the stage of dropsy. Haemoptysis rarely requires special treatment but if it is severe bed rest is necessary. Bacterial endocarditis requires treatment with appropriate antibiotics (see p 888). The treatment of embolic episodes depends on the site of embolism and severity of ensuing ischaemia. Embolectomy is almost never necessary in the arm but is occasionally advisable if the site of embolism can be accurately located in the femoral or popliteal vessels. A saddle embolism at the aortic bifurcation should be removed if the peripheral effects indicate great obstruction. Auricular fibrillation marks a definite stage in the deterioration of patients with mitral stenosis and little is gained by attempts to restore the rhythm with quinidine unless mitral valvotomy has been performed.

MITRAL VALVOTOMY

SELECTION OF CASES—Mitral valvotomy is indicated in all patients in whom serious obstruction to the flow of blood through the stenosed mitral valve is the dominant functional disorder. The selection of patients can usually be made by clinical examination alone aided by electrocardiography and radiographic screening and only rarely is it necessary to perform cardiac catheterisation in their pre operative assessment. Contraindications to operation are of two types. The stenosis may not be of sufficient degree to warrant operation or mitral stenosis may be complicated by other factors and hence is no longer the dominant functional disorder.

Patients with a minor degree of mitral stenosis are not troubled with dyspnoea and hence the history is of great importance in assessing the severity of the lesion. In those with serious mitral valve obstruction symptoms are always present the commonest being exertional dyspnoea, paroxysmal nocturnal dyspnoea or recurrent haemoptyses. An attempt should be made to assess the degree of exertional dyspnoea for this is often a rough guide to the degree of stenosis. The patient's ability to

perform ordinary daily routine tasks is a useful yardstick. In doubtful cases in which functional overlay is suspected in the patient's symptoms, a simple exercise test on stairs will often help to evaluate the disability.

Age is an important factor in the selection of patients. The older patients in whom a greater degree of coronary and cerebral atherosclerosis may be expected do not respond as well to valvotomy as those in the younger age groups. On the whole 50 years should be considered the upper age limit, although no hard-and-fast dividing line should be drawn, and a patient's cardio-vascular age as well as his chronological age should be taken into account. In view of the greater likelihood of recurrent attacks of rheumatic fever in patients under the age of 20 years, it is probably undesirable to operate in this age group. If, however, mechanical obstruction at the mitral valve is sufficient to cause congestive cardiac failure or pulmonary oedema, mitral valvotomy should be performed even in this age group.

Chronic congestive cardiac failure of several years' duration, not responding to medical treatment, is usually associated with considerable cardiac dilatation and myocardial failure. In such cases relief of the mechanical obstruction of the mitral valve does little to relieve heart failure. Great enlargement of the left auricle to giant or aneurysmal proportions is another contraindication to valvotomy. These large auricles are often lined with mural thrombus and the danger of detaching a small piece at operation and hence risking a cerebral embolus is considerable. In addition, in "giant left auricle" mitral regurgitation rather than stenosis is usually the dominant lesion. A small degree of aortic incompetence complicating dominant mitral stenosis is no contraindication to mitral valvotomy, but where such a lesion has given rise to left ventricular enlargement, operation is contraindicated. In the presence of aortic stenosis sufficient to cause left ventricular enlargement, mitral valvotomy should not be considered, except in conjunction with aortic valvotomy. Functional pulmonary incompetence secondary to pulmonary hypertension is no contraindication to mitral valvotomy. Likewise tricuspid stenosis, or regurgitation of minor degree, is no bar to the operation. Where mitral regurgitation complicates mitral stenosis the decision as to whether valvotomy will help the patient depends on which lesion predominates functionally. A minor degree of mitral regurgitation associated with severe stenosis is compatible with excellent results after mitral valvotomy.

Auricular fibrillation should not influence the decision as to whether the patient should have a valvotomy, although better results are usually obtained in patients with sinus rhythm. Calcification of the mitral valve, although often causing the actual valvotomy to be technically more difficult, does not prevent an excellent result from the operation.

Pulmonary hypertension of varying degree is present in most cases suitable for valvotomy, but a normal pulmonary artery pressure at rest may coexist with severe mitral stenosis. The absence of pulmonary hypertension therefore does not indicate that the case is unsuitable for surgery, and indeed it is especially in the group of patients with tight stenosis and only moderate pulmonary hypertension that fatal pulmonary oedema is prone to occur if surgery is delayed.

PRE-OPERATIVE CARE.—In the absence of congestive cardiac failure, little special pre-operative treatment is required. Pre-operative digitalisation, in patients in sinus rhythm and not already digitalised, is usually employed as a prophylactic measure against the sudden onset of rapid auricular fibrillation, during or immediately after the operation. Routine treatment of congestive cardiac failure is indicated with digitalis, Neptal and low salt diet as required. In patients confined to bed with congestive failure, calf vein thrombosis and pulmonary emboli may occur and these will call for anti-coagulant treatment. In bronchitic patients, in addition to routine pre-operative breathing exercises, antibiotics and antispasmodic drugs should be given.

The operation.—The usual route of entry into the left auricle at operation is through

the left auricular appendage. Where this is too small or filled with organised clot entry may be made through the wall of the left auricle using a tourniquet or through a pulmonary vein. The valvotomy can usually be satisfactorily performed by splitting the adherent commissures with the finger. Only in cases in which dense fusion has occurred is the use of a valvotome necessary. The degree of mitral stenosis and the degree of associated regurgitation if any can be assessed by the surgeon's palpating finger.

An intravenous procaine drip is often given in an attempt to damp cardiac irritability and thus avoid serious cardiac arrhythmias. Ventricular fibrillation and ventricular arrest are rare but serious complications during the operation itself. Cardiac massage and in some cases an electrical defibrillator are indicated.

POST OPERATIVE COMPLICATIONS—Auricular fibrillation may occur for the first time in the immediate post operative period and is commonest during the first 14 days. Reversion to sinus rhythm may be attempted with quinidine in some cases this reversion occurs spontaneously.

A traumatic pericardial effusion sometimes develops and this may give rise to subacute pericardial tamponade during the first or second post operative week. Pericardial effusions are less frequent if local intrapericardial procaine is avoided at operation and adequate dependant drainage into the pleural cavity allowed for when the pericardium is sutured. Post operative mitral regurgitation where none was present pre operatively is rarely produced when the finger alone splits the commissures of the valve at their line of fusion. After the use of a valvotome post-operative regurgitation has been reported more frequently although it is seldom of any serious functional significance.

Cerebral emboli or emboli elsewhere originating from particles of clot detached from the intra auricular thrombus or from calcified masses on the valve itself may occur at the operation or in the immediate post-operative period.

RESULTS—In most reported series of patients treated by mitral valvotomy results are classed as excellent in about a quarter of cases, in about a half they are good while in the remaining quarter improvement if any is poor. The mortality rate is about 5 per cent. An excellent result indicates that the patient is able to return to full work again and even to enjoy sports such as swimming and cricket.

It is too soon yet to assess the long term prognosis but in a few instances the valve cusps have become adherent again within the first 3 years of the original operation and a second valvotomy has been necessary. Fortunately such cases have so far proved rare.

AORTIC STENOSIS

Narrowing of the aortic orifice to one quarter or less of its normal size causes symptoms and signs from the decreased cardiac output, decreased coronary flow and left ventricular hypertrophy which eventually results in failure of the myocardium to overcome the obstruction.

Ætiology—The ætiology in most cases is rheumatic and the aortic stenosis is frequently combined with aortic incompetence and mitral stenosis. In many cases of pure or predominant aortic stenosis a murmur has been heard at a very early age and a congenital origin has been suggested for this. This is further supported by the rarity of a history of rheumatism in such cases and by a striking predominance of males (about 3 to 1) compared with the female dominance in mitral stenosis. With the development of more accurate criteria for diagnosis aortic valve stenosis has been found to be common. Congenital subaortic stenosis is excessively rare and cannot be distinguished clinically from the valvular variety. Syphilis is never a cause of narrowing of the aortic valve.

Pathology—The aortic cusps are thickened and deformed and often joined

together. In severe cases the identity of the cusps is lost and only a narrow crescentic or triangular orifice is left. Extensive calcification is almost invariable in the older age groups. Beyond the obstruction the aorta often shows a local area of dilatation. The aorta and the coronary arteries are strikingly free of atheroma. There is usually considerable hypertrophy of the left ventricle and the heart may weigh between 500 and 700 g. Dilatation of the ventricle is usual, though late, and some interstitial fibrosis of the myocardium occurs.

Symptoms and Signs—Slight or moderate aortic stenosis causes no symptoms. Severe aortic stenosis causes striking and characteristic symptoms which tend to appear in middle life, and late in the course of the disease. Shortness of breath on exertion is usually the first symptom and gradually progresses until left ventricular failure causes paroxysmal nocturnal dyspnoea (see Left Ventricular Failure, p. 809). Cardiac ischaemic pain on effort is caused by the diminished coronary flow and is indistinguishable from angina pectoris due to coronary disease. The reduced cardiac output is responsible for attacks of dizziness, "blackout", or even syncope which is characteristically provoked by effort, but these symptoms may occur as a result of changes in posture, or peripheral vasodilatation. Sometimes no provoking cause can be discovered, and syncopal attacks may be severe and frequent.

Characteristic abnormalities are found on examination of the pulse, on palpation of the heart and on auscultation. All these abnormalities are required for the firm diagnosis of aortic stenosis. The pulse is small and rises slowly, and pulse tracings frequently show a notch on the ascending limb (anacrotic pulse). The blood pressure is normal or low. The venous pulse is normal in form and in pressure. On palpation the apex beat may be displaced to the left, but, far more important, its character changes to an obvious and sustained heave, indicating hypertrophy of the left ventricle. On auscultation there is an obvious systolic murmur in the aortic area which may be loud enough to produce a thrill and is well transmitted to the neck. The same murmur is transmitted to the apex where it may be as loud as in the aortic area, and occasionally the murmur is loudest at the apex. In many cases the systolic murmur is no more than moderately loud, and does not produce a thrill. The murmur is due to the flow of blood through the narrow, distorted valve. It starts at the moment of ejection, rises to a crescendo in mid systole and diminishes as the flow diminishes, ceasing before the second sound. This mid systolic pattern, which can be detected with the stethoscope, is common to all systolic murmurs produced during ejection through the aortic (or pulmonary) valve and does not mean stenosis unless accompanied by the abnormal pulse and hypertrophy of the left ventricle. The aortic component of the second sound may be soft or absent, but it is frequently normal and can be clearly heard at the apex where the pulmonary component of the second sound is not normally transmitted. Physiological splitting of the second sound in the pulmonary area, due to inspiratory delay of the pulmonary component, is seldom heard in aortic stenosis. This may be due to prolongation of left ventricular systole making the two sounds coincide, or to reversal of the normal order of valve closure making the earlier pulmonary component difficult to detect in the systolic murmur. A faint aortic diastolic murmur indicating a minor degree of aortic incompetence is not uncommon.

The electrocardiogram is useful in assessing the degree of left ventricular hypertrophy and therefore the severity of the aortic obstruction. Deep S-T depression and I wave inversion are a feature in chest leads taken over the left ventricle, and this pattern with a tall R wave is frequently transmitted to both the left arm and left leg, making all three standard limb leads of a similar pattern. There may be left bundle branch block. The rhythm is usually normal, but prolonged auriculo-ventricular conduction and dissociation are not uncommon. On radiography the left ventricle may be enlarged but evidence of hypertrophy is usually found earlier by electrocardiography and by palpation. The ascending aorta can usually be seen to

be dilated immediately distal to the valve. Calcification of the aortic valve can be detected by fluoroscopy in a very high proportion of the older patients

Complications—Bacterial endocarditis may occur at any time in the course of the disease, even in the early stages when the only physical sign is a mid systolic murmur (see p 886) Sudden death is not infrequent once symptoms have developed

Course and Prognosis.—The course of patients with aortic stenosis is long and benign. A systolic murmur may have been heard in childhood and passed as innocent, and the stenotic pulse and left ventricular hypertrophy may not develop until middle age. Once symptoms of cardiac failure have been noticed, the course is usually downhill. Shortness of breath on exertion is succeeded by paroxysmal nocturnal dyspnea from left ventricular failure, pulmonary congestion and congestive heart failure ensue. In some cases raised jugular venous pressure and oedema may appear without preceding symptoms of left ventricular failure (Bernheim's syndrome) and this is probably due to interference with the capacity of the right ventricle owing to encroachment by the massive hypertrophy of the left ventricle. Angina pectoris and syncope on effort adversely affect prognosis and sudden death is not uncommon.

Diagnosis—A diagnosis of aortic stenosis is made by finding a slow rising pulse, an aortic systolic murmur and evidence of left ventricular hypertrophy. In hypertension with aortic dilatation there may be left ventricular hypertrophy and a soft aortic systolic murmur but no stenotic pulse. In dilatation of the aorta from atheroma alone there may be a soft aortic systolic murmur but no abnormal pulse or left ventricular hypertrophy.

In acute rheumatism with aortic valvulitis without stenosis there is a soft or moderately loud aortic systolic murmur but no abnormal pulse or evidence of left ventricular hypertrophy. In aortic incompetence there is usually an aortic systolic murmur, and when associated with aortic dilatation as in syphilis, there may be a loud systolic murmur and even a thrill, but the pulse is waterhammer and the left ventricle feels hyperdynamic as well as hypertrophied. Differentiation from mitral incompetence can be difficult since in both conditions there may be a loud apical systolic murmur. The systolic murmur in mitral incompetence is always pansystolic often with a crescendo in late systole obliterating the second sound at the apex, though this sound is clear enough elsewhere. The mitral systolic murmur is not loud in the aortic area and is frequently better conducted to the axilla and back. In mitral incompetence the pulse is not anacrotic unless there is associated aortic valve disease.

Treatment—No treatment is necessary for cases of mild or moderate aortic stenosis except to avoid hard physical effort, especially competitive games. Reassurance and encouragement can benefit many of these patients. In severe aortic stenosis with ischaemic pain, or syncopal attacks exertion sufficient to produce symptoms must be strictly avoided, and this is usually compatible with a sedentary occupation. Left ventricular failure is treated with digitalis, a low sodium diet and mercurial diuretics (see p 812). Some patients have been successfully treated by aortic valvotomy but the value of this operation cannot yet be assessed.

AORTIC INCOMPETENCE

Damage to the aortic cusps, a dilated valve ring or a combination of these circumstances leads to aortic incompetence. The magnitude of the backflow varies from a small fraction to half of the stroke output when the cusps are totally deficient, this regurgitated blood increases the residual left ventricular volume and stretches the myocardium, causing a more vigorous contraction of the left ventricle and a steep rise of intraventricular pressure resulting in early ejection of an increased volume of blood. This steep rise of pressure imparts a "hyperdynamic feel" to the apex beat, which is transmitted to the carotid arteries where it is known as Corrigan's sign, to

the peripheral arteries causing a waterhammer pulse, and to the capillaries where the increased pulsation may be seen. The increased left ventricular volume causes dilatation, and the increased work causes hypertrophy of the left ventricle which may reach an enormous size.

Ætiology and Pathology.—Rheumatic valvulitis is by far the commonest cause of aortic incompetence in Great Britain, and in most cases there is additional involvement of the mitral valve. Syphilitic aortic incompetence is now less commonly seen (see p. 859); here the main damage is in the aorta, causing dilatation of the aortic ring, and severe involvement of the cusps is much less common. Syphilitic aortitis also results in aneurysm formation, coronary ostial stenosis leading to cardiac ischæmia and, rarely, cardiac infarction. In severe hypertension stretching of the aortic ring may cause a minor degree of incompetence. Damage to the aorta from a dissecting aneurysm occasionally causes aortic incompetence. Bacterial endocarditis is rarely the primary cause, although it may increase pre-existing damage and is the commonest cause of a ruptured aortic cusp. Congenital bicuspid aortic valves, or rarely, quadricuspid valves, tend to be incompetent when associated with hypertension or atheroma. A minor degree of incompetence from a bicuspid valve is frequently found in patients with coarctation of the aorta. Congenital abnormalities of the aortic valve causing incompetence are occasionally associated with large ventricular septal defects or other more serious forms of congenital heart disease.

Symptoms and Signs.—A slight or moderate degree of aortic incompetence usually produces no symptoms for many years, especially if it is of the rheumatic variety. Shortness of breath on exertion is the first significant symptom and, as with aortic stenosis, left ventricular failure tends to progress rapidly with paroxysmal nocturnal dyspnoea and cardiac asthma. Ischæmic pain is not uncommon, especially in the syphilitic group with coronary ostial stenosis, and the pain tends to occur during an attack of paroxysmal nocturnal dyspnoea.

The pulse of aortic incompetence rises steeply in systole and gives a characteristic tap to the palpating finger which is described as simulating a waterhammer. The rapid fall of pressure is described as collapsing. These signs are best appreciated by palpating the radial and brachial arteries with the flat of the fingers when the arm is elevated. The same pulsation can be seen in the carotid arteries as described by Corrigan, and in the capillaries especially of the nail bed. The compensatory rise in systolic pressure and low diastolic pressure from the aortic backflow and peripheral vasodilatation produces a wide pulse pressure, and a blood pressure of about 180/50 is not uncommon. There may be difficulty in estimating the diastolic pressure, and persistence of the diastolic sound down to zero does not indicate a diastolic pressure at this level. The apex is heaving from left ventricular hypertrophy and the sudden steep lift in systole combined with a second small wave in diastole gives the apex a hyperdynamic quality. The apex is displaced downwards and to the left. On auscultation there is an early diastolic murmur commencing immediately after the aortic component of the second sound. This murmur is high pitched and best heard with the diaphragm type of stethoscope. It is usually maximal to the left of the sternum in the third and fourth left spaces over the aortic valve, but when the ascending aorta is dilated, especially in syphilitic aortitis, the murmur is often loudest to the right of the sternum. Early diastolic murmurs may be very difficult to hear, but they are usually more easily heard on expiration, in the sitting position, and when the heart is slowing after exertion. An aortic systolic murmur is usually heard, and is of the same quality as in aortic stenosis but is not so loud. Occasionally the systolic murmur may be loud, and even associated with a thrill when the first part of the aorta is greatly dilated from syphilitic aortitis. Wide splitting of the first heart sound is not unusual, and is due to the addition of an extra ejection sound in early systole from dilatation of the aorta. In some patients with isolated free aortic incompetence a rumbling mid-diastolic murmur, with or without a presystolic murmur,

is heard at the mitral area and is known as the Austin Flint murmur. It has been ascribed to the regurgitant stream from the aortic valve pushing back the aortic cusp of the mitral valve in diastole, so that it causes some obstruction to the mitral orifice. However, in many cases the auscultatory impression of a mid-diastolic murmur is caused by the addition of a third heart sound from left ventricular failure.

→ The electrocardiogram shows left axis deviation, tall R waves, depression of S-T segments and T wave inversion in leads over the left ventricle when this is hypertrophied, but it is normal when the aortic incompetence is slight. → On radiography there is great enlargement of the left ventricle in severe cases, and obvious uncoiling of the aorta even in the rheumatic cases. Aortic pulsation is greatly increased. There is no calcification of the aortic valve.

Complications — Bacterial endocarditis can occur at any time in the rheumatic group but is extremely rare in the syphilitic cases. Rupture of a damaged aortic cusp is usually due to superimposed bacterial endocarditis, and tends to be a serious complication owing to the increase in strain on the left ventricle. Recurrence of active rheumatic carditis may precipitate heart failure.

Diagnosis — The diagnosis of aortic incompetence is made by hearing an aortic diastolic murmur, and in mild cases this may be the only physical sign. It may be difficult to distinguish from a pulmonary diastolic murmur but the latter is almost confined to patients with great pulmonary hypertension with its characteristic physical signs. In severe aortic incompetence the combination of a waterhammer pulse, enlarged left ventricle and early diastolic murmur are characteristic. It may be much more difficult to decide the aetiology. Syphilitic aortic incompetence is favoured by an age of over 35 years, a positive history of infection, ischaemic cardiac pain, a positive Wassermann reaction and by signs of syphilis elsewhere. An aortic aneurysm indicates luetic aetiology, but it must be remembered that free rheumatic aortic incompetence may cause great dynamic unfolding of the aorta, this always appears symmetrical and involves the ascending part, arch, and upper descending aorta equally, while syphilitic dilatation is irregular (see p 860). An incorrect diagnosis of additional mitral stenosis, and therefore of a rheumatic aetiology, may be made by hearing an Austin Flint murmur and by seeing apparent enlargement of the left auricle in the right oblique view, on the X ray screen, this is due to enlargement of the left ventricle which displaces the auricle backwards. When heart failure has ensued left auricular and right sided enlargement may further simulate the effect of additional mitral stenosis. Rheumatic aortic incompetence can be diagnosed with confidence under the age of 30 years. The diagnosis of additional mitral stenosis confirms a rheumatic aetiology, and this can be made with confidence when there is a loud first sound, an opening snap and a mid diastolic murmur. A pansystolic murmur at the apex, with systolic backward movement of the left auricle, favours additional organic mitral valve disease, but when there is great left ventricular enlargement from aortic valve disease a mitral systolic murmur may be due to functional mitral incompetence. Calcification of the mitral valve, but not of the annulus, indicates a rheumatic aetiology. Occasionally the murmurs of aortic incompetence may be simulated by pericardial friction in acute pericarditis. The peripheral signs of aortic incompetence are present in patent ductus arteriosus, and occasionally the murmur of this condition may be confused with the "to and fro" murmur of aortic incompetence. However, in patent ductus arteriosus the characteristic continuous murmur is best heard in the second left intercostal space. The left ventricle is usually not greatly hypertrophied and on X-ray screening there is pulmonary plethora. In occasional cases cardiac catheterisation is necessary to establish the diagnosis of patent ductus arteriosus.

AORTIC STENOSIS WITH INCOMPETENCE — A combination of stenosis and incompetence is frequent when the aetiology is rheumatic, and incompetence in the younger age groups may change to dominant stenosis in later years. The physical signs of

both valve lesions may be present and the pulse frequently has a double impulse (pulsus bisferiens).

Prognosis.—Minor degrees of aortic incompetence are compatible with a long and full life. Severe aortic incompetence causes great strain on the left ventricle and once symptoms have started, the downhill course is usually rapid as in aortic stenosis. Heart failure occurs with normal rhythm. Prognosis depends on the degree of incompetence as judged by peripheral signs and cardiac enlargement. The outlook of patients with rheumatic aortic incompetence is better than those with syphilitic aortitis.

Treatment.—Treatment is the same as for aortic stenosis except that surgical repair promises to be more difficult. The onset of breathlessness indicating left ventricular failure should be taken seriously; a full 3 weeks' rest in bed is advisable and a low sodium régime is indicated (see treatment of left ventricular failure, p. 812).

TRICUSPID VALVE DISEASE

Functional tricuspid incompetence is a common condition: it results from dilatation of the right heart and thus usually accompanies congestive heart failure. Organic tricuspid valve disease is mostly due to chronic rheumatic valvulitis. It is much less common than chronic mitral valve disease with which it is usually associated. Some degree of tricuspid valvulitis is present in about one-third of cases of chronic rheumatic valvulitis at necropsy. Tricuspid stenosis is rarely due to congenital malformation, but tricuspid incompetence may result from a curious congenital malformation (Ebstein's disease) in which the cusps of the valve are incompletely formed or displaced into the right ventricular chamber. In general the pathological findings in organic tricuspid valve disease are the same as in mitral valve disease: in the rare, pure tricuspid valve lesions, however, the left heart and the lungs are relatively normal.

Symptoms.—The symptoms are those of progressive right heart failure, but as most cases are associated with mitral stenosis, there is dyspnoea on effort in addition to weakness. Tricuspid valve disease tends to prevent all forms of paroxysmal dyspnoea; indeed when functional tricuspid insufficiency develops in left ventricular disease or mitral stenosis, the patient is often relieved of cardiac asthma. In tricuspid valve disease severe symptoms may develop from extreme congestion of all organs; dyspepsia, pain in the right hypochondrium and insomnia are common features.

Signs.—In advanced chronic tricuspid valve disease, wasting, slight icterus, peripheral cyanosis, hepatomegaly and recurrent ascites are commonly present. Tricuspid incompetence causes an increased venous pulse wave which is coincident with ventricular systole ("cv" wave); it appears to rise rather slowly in the neck veins in contrast with augmented auricular waves. The systolic venous pulse wave is associated with systolic expansile pulsation of the liver when tricuspid incompetence is great. This sign is elicited by bimanual examination of the liver, one hand being placed behind and the other in the epigastrium. Various murmurs are frequently present from associated valve lesions, but the systolic murmur of tricuspid incompetence may be distinguished; it is pansystolic, heard best inside the apex or at the lower end of the sternum and its intensity varies with respiration, being louder in inspiration.

Tricuspid stenosis causes an augmented auricular wave ("a" wave) in the venous pulse—this wave is short, quickly rising, of variable amplitude and presystolic in time. A tricuspid diastolic murmur may be present; it is best heard at the lower end of the sternum and is loudest in inspiration, but as the lesion is mostly associated with mitral stenosis, it is not usually possible to distinguish with certainty the right and left heart murmurs.

The outstanding feature of tricuspid valve disease on radiography of the heart is right auricular enlargement—in some cases the right auricle may appear to occupy most of the enlarged heart shadow. Radiographic screening sometimes shows systolic

pulsation of the right auricle in tricuspid incompetence, but more often the auricle is so large that the regurgitant stream produces little movement, however, appropriate auricular or ventricular pulse waves may be seen in the superior vena caval shadow. The lungs are frequently clear in spite of the degree of heart disease.

Diagnosis—Careful observation of the venous pulse is the key to diagnosis in tricuspid valve disease. Tricuspid incompetence is frequently overlooked because of the dominant signs of associated organic heart disease. Tricuspid stenosis is relatively rare—it should be considered in chronic rheumatic heart disease when there are signs of right heart failure, recurrent ascites and hepatomegaly. If the heart rhythm is regular, large auricular waves in the neck veins and presystolic hepatic pulsation are diagnostic signs.

Prognosis—The prognosis in functional tricuspid incompetence is essentially that of the causal disease. In organic tricuspid disease prognosis also largely depends on the degree of associated chronic mitral valvulitis and its effect on the whole heart.

Treatment—The treatment of functional or organic tricuspid incompetence is the treatment of heart failure. The rare cases of pure or dominant tricuspid stenosis should be treated by tricuspid valvotomy.

DISEASES OF THE PERICARDIUM

PERICARDITIS

Inflammation of the pericardium may be acute or chronic and occurs as a primary infection or as part of a general disease. The acute form may be dry (fibrinous) or accompanied by effusion (serous). Chronic pericarditis occurs as constrictive pericarditis, adhesive mediastino pericarditis and rarely as a chronic effusion. The important considerations in all forms are the nature of associated disease, and the presence of circulatory embarrassment through interference with diastolic filling and ventricular systole.

ACUTE PERICARDITIS

Ætiology.—The age and sex incidence in acute pericarditis depends on the nature of the cause. It is frequently due to acute rheumatic fever, and sometimes to pyogenic bacterial infections and tuberculosis. Idiopathic or acute benign pericarditis is probably due to a virus infection. Other causes are uræmia, trauma and invasion by neoplasm. Acute pericarditis frequently results from cardiac infarction.

Pathology—The morbid anatomical findings largely depend on the ætiology of the pericarditis. The acute fibrinous forms may be local or general in distribution. In the early stages the pericardium loses its smooth, shiny appearance because of a surface exudate of lymph, fibrin and inflammatory cells. This exudate may become thick and irregular, resulting in a ragged, honeycombed appearance—the so-called "bread and butter pericardium". In many cases the superficial layers of the myocardium also show an inflammatory reaction. Organisation takes place leaving varying degrees of slight pericardial thickening, often with adhesions. In other forms the fibrinous reaction may be associated with a large effusion of serous or sero-sanguinous or sero-purulent fluid, and occasionally the sac may be full of pus.

Clinical Features—1 *Acute fibrinous pericarditis (i.e. without effusion)*.—In many cases there are no symptoms, in others the symptoms are submerged in those of associated disease, i.e. rheumatic carditis and cardiac infarction, whilst in others distinctive features are present.

Pain varies in intensity and is situated across the front of the chest, sometimes radiating to the neck, shoulders and arms, it may occasionally be confined to the epigastrium. Pericardial pain may be indistinguishable from the pain of cardiac

infarctioo, but sometimes it is made worse by moving the chest, especially into the hyperextended position, and on deep breathing. It is generally agreed that the visceral pericardium is insensitive and the pain of pericarditis appears to arise from the parietal pericardium and its area of continuity with the diaphragm and pleura. Some degree of dyspnoea is usual, but this is not a prominent feature unless there is pericardial effusion.

There is often moderate fever, sweating and a leucocytosis, depending on the aetiology of the pericarditis. The characteristic physical sign is a friction rub which occurs in systole and diastole, giving it a "to and fro" character, which sometimes resembles the murmur of aortic stenosis and incompetence. Friction rubs are best heard towards the base. They have a superficial scratching quality and vary in intensity with pressure of the stethoscope, they are often transient and generally disappear when an effusion develops.

2 Pericarditis with effusion—The clinical picture varies with the amount of fluid and the rate at which it accumulates. If the amount is small there may be no symptoms. If, on the other hand, it is large and the accumulation is rapid, pain is usual and the patient is often anxious, restless and pale. The pain may be severe, but there is more often a sense of dull sternal oppression. Dyspnoea and orthopnoea develop in proportion to the size of the effusion and appear to be due to a direct compression of adjacent lung and diminution of vital capacity. An irritating cough occurs with large effusions. Cardiac asthma sometimes occurs, but is probably due to underlying myocardial disease.

A friction rub is sometimes heard towards the base of the heart. The apex beat becomes weak and may disappear, and the heart sounds are soft at the apex. The extent of cardiac dullness increases and is said to vary with the posture of the patient. In large effusions dullness to percussion and bronchial breathing occur posteriorly over the left lower lobe, due to partial or complete atelectasis.

The interference with cardiac function known as *cardiac tamponade* which occurs in many cases is related to the size of the effusion and its rate of development. The clinical features of tamponade are due to restriction of diastolic filling and consequent reduction in cardiac output, a rise in right auricular pressure above the pericardial pressure, and peripheral vasoconstriction which maintains blood pressure in the presence of a falling cardiac output. Tamponade is recognised by a rising jugular venous pressure and this should be carefully assessed in all cases of suspected pericardial effusion. The systemic blood pressure tends to fall and the radial pulse may become very small—occasionally it fades during inspiration (*pulsus paradoxus*). A paradoxical rise of venous pressure with inspiration may be observed in the jugular veins. Tachycardia is usual. Rapidly developing tamponade may lead to shock, whilst a slowly increasing pericardial effusion may produce widespread venous congestion resembling congestive heart failure.

The radiology of acute pericarditis—Radiological changes in acute pericarditis occur when an effusion collects in the sac. The important signs are (1) an enlargement of the heart shadow and a decrease in size with recovery shown by serial films, (2) a rounding of the heart shadow, becoming almost globular in some cases, with obliteration of the normal angulation along the left border, sharpening of the pericardiophrenic angles and a bulging into the retrocardiac space best seen in the right oblique view, (3) diminution of cardiac pulsation seen on radioscopy—in extreme cases the shadow appears quite still, (4) on cardiac catheterisation there is a space between the catheter tip lying against the right auricular endocardium and the outer border of the heart. This increase in thickness of the wall due to fluid may be clearly demonstrated by angiocardiology—a small quantity of dye introduced through a catheter is sufficient for diagnostic purposes.

The electrocardiogram in acute pericarditis tends to show pathological changes in all leads due to the widespread nature of the injury. The time relations of various

complexes remain normal P waves are unaffected The QRS complex remains normal in form but the voltage is frequently diminished in all leads in pericardial effusion The important pathological changes in pericarditis are due to epicardial injury and are found in the S T segment and T waves The S-T segment is slightly elevated in all leads showing more in some leads than in others Usually the S T is concave upwards in others it is straighter and occasionally coved with a convexity upwards as is found in myocardial infarction These changes fluctuate, tend to be transient and rarely last for more than 10 days The T waves tend to become flattened and inverted A small inversion of T waves in all standard leads and chest leads is sometimes seen—the widespread nature of such a change is strong evidence of pericarditis Occasionally the T wave is tall and sharp at the termination of a raised concave S T segment

The electrocardiogram of cardiac infarction is partly due to epicardial disease so that differentiation from pericarditis is sometimes difficult The changes in pericarditis are more diffuse and are never associated with Q waves An isolated steep inversion of T waves occurring in only one or two leads is not due to pericarditis

Paracentesis of the pericardium is indicated when diagnosis remains in doubt, when examination of the fluid is required for diagnosis of the cause and as an urgent therapeutic measure when cardiac tamponade is great or increasing rapidly

The skin and underlying tissues should be anaesthetised down to the pericardium The needle should be inserted just beyond the apex beat or high in the angle between the ensiform cartilage and the left margin of the sternum and then passed upwards backwards and slightly to the right the needle should be withdrawn a little when pulsation of the heart is felt on reaching the epicardium Sufficient fluid is withdrawn for diagnostic purposes or to relieve symptoms This procedure is not indicated unless there is evidence of a considerable quantity of fluid or severe tamponade

SPECIAL TYPES OF PERICARDITIS—1 *Acute benign pericarditis* (idiopathic pericarditis non specific pericarditis or virus pericarditis)

This condition is of considerable importance because it is readily mistaken for cardiac infarction Adults of either sex are affected the aetiology is unknown but an upper respiratory tract infection or pneumonitis frequently precedes the pericarditis A moderate sized effusion may develop friction may appear and fever may last a few days The condition lasts for days or weeks but relapse is not uncommon however recovery is invariable and apparently complete

2 *Tuberculous pericarditis*—This is a relatively rare clinical condition It usually appears to be the primary manifestation of tuberculosis but in most cases it is secondary to an obscure lesion elsewhere The onset is often insidious with general symptoms rather than local ones due to pericarditis Chest pain usually develops but may be transitory cough is common and fever is high and irregular but may be completely absent in elderly patients Signs of tamponade develop and cardiac arrhythmias are common The tuberculous aetiology may be confirmed by examination of aspirated pericardial fluid The prognosis is bad without treatment mortality rate in the first year after the onset of symptoms being approximately 50 per cent Surviving patients whether treated or untreated may develop constrictive pericarditis later

Treatment—Prolonged bed rest similar to sanatorium régime is necessary The prognosis is greatly improved by the concurrent administration of 1 g. of streptomycin intramuscularly and 12 g. of sodium aminosalicylate (P A S) daily for 120 days Streptomycin can also be combined with isoniazid When pericardial aspiration is possible and indicated by the size of the effusion 1 g. of streptomycin in saline should be injected into the sac This procedure may be repeated at weekly intervals and good results have been obtained The treatment of tuberculous pericarditis is still largely experimental and various combinations of chemotherapeutic drugs merit a trial There is some evidence that early surgical drainage after treat

ment with streptomycin may be beneficial. The progress of treatment is assessed from the degree of fever, improvement in general symptoms, the erythrocyte sedimentation rate, radiological heart size and the electrocardiogram.

3 Rheumatic pericarditis—Some degree of transient fibrinous pericarditis probably occurs in a majority of cases of rheumatic carditis and its significance is subordinate to the whole disease. In some cases, however, usually the more serious ones, an effusion develops and this adversely affects the course of the disease.

4 Purulent pericarditis is fortunately rare now that the pyogenic conditions which cause it are treated with antibiotic agents or chemotherapy. Surgical drainage together with the appropriate chemotherapy is indicated.

Diagnosis—Chest pain, a friction rub, fever and widespread S-T elevation and T wave changes in the electrocardiogram are the diagnostic features of acute fibrinous pericarditis, but these features do not always occur together. Pain is often absent, friction rubs are often fleeting, fever may be absent or due to associated disease and the electrocardiogram may be pathological only for a brief period. When pain, friction or electrocardiographic changes occur in the course of a disease known to be complicated by pericarditis, such as rheumatic fever, septicæmia, chest neoplasm and uræmia, the diagnosis is readily made.

The accumulation of pericardial fluid is recognised by radiographic change in heart shape, softening of the heart sounds, electrocardiographic changes and the signs of developing tamponade. The withdrawal of pericardial fluid by paracentesis is diagnostic and helps in the investigation of its ætiology. Repeated physical examinations, serial electrocardiograms and chest films are of great importance, not only for observing the progress of the disease, but for diagnostic purposes.

The important differential diagnosis of acute virus pericarditis is cardiac infarction (see above). Congestive cardiac failure must be differentiated from pericardial effusion causing tamponade. Here a knowledge of the underlying ætiology, the radiographic features, serial electrocardiograms and special investigations mentioned above for pericardial effusions are of diagnostic importance. The prognosis and treatment of acute pericarditis depend on the underlying cause.

CHRONIC CONSTRICTIVE PERICARDITIS

Synonym—Pick's Disease

This condition is essentially one of great thickening of the pericardium, which imposes a restrictive action on the heart so that diastolic filling is impeded, systolic ejection is diminished and venous congestion develops. It was known long before a series of cases were described by Pick in 1896. There are descriptions by Lower and by Lancisi over a century before, and Chevers discussed the pathophysiology of the condition in 1842.

Ætiology—Constrictive pericarditis occurs in men more often than in women and mostly between 15 and 40 years of age.

It is not surprising that the ætiology is difficult to find since it is not until healing and organisation of previous inflammation have taken place that the condition comes into existence. Probably many cases are due to tuberculosis, but a definite history of previous pericarditis is rare and tuberculosis can only be demonstrated in some 16 to 20 per cent of biopsy or necropsy specimens by histological and bacteriological methods. Rarely inflammation with pyogenic organisms may produce constrictive pericarditis, and it may also occur as a result of organisation of hæmopericardium.

Pathology—The heart is encased in pericardium which is thickened from 2 to 10 mm. This scar tissue shows varying degrees of hardness from an heterogeneous fibro-carcous mass to hard homogeneous hyalinised tissue or dense fibrosis with extensive calcification. This compression scar usually encases most of the heart and

sometimes extends up to the great vessels, but occasionally it is more localised. The heart is essentially normal, but the superficial myocardium is frequently involved in the overlying pericarditis so that a line of cleavage cannot be found.

The serous cavities usually contain effusions and the peritoneum is often thickened, sometimes to the extent of producing a so-called "sugar-icing" appearance. The liver shows the results of long-standing venous congestion, it may be large or normal sized with a nutmeg appearance, or shrunken and fibrotic. It appears that the cirrhotic process continues after surgical relief of the constrictive pericarditis, if it has developed sufficiently to produce its own effects.

Clinical Features.—The clinical features are the result of restricted diastolic filling especially of the right heart, which causes a reduction in cardiac output, this leads to sodium and water retention. The resulting hypervolaemia means an increased venous return which, however, cannot be accommodated by the constricted ventricles so that extreme venous congestion results.

Constrictive pericarditis develops quietly and symptoms are not usually prominent until the signs are well developed. The patient may first complain of dyspnoea on effort or swelling of the abdomen. Sometimes cough is a prominent feature and occasionally faintness on bending down or coughing may be troublesome.

The most important physical sign is congestion of the cervical veins—this may be so great that the top level of venous pulsation is well above the ears and cannot be seen (20 to 30 cm. above the right auricle is usual). The venous pulse wave form appears continuously high with sharp descents in early diastole and a paradoxical rise in venous pressure with inspiration is usually present. Constrictive pericarditis does not occur without venous hypertension. The arterial pulse tends to be small and often shows a diminution with inspiration (pulsus paradoxus). The blood pressure is usually low, peripheral arterial constriction shown by peripheral cyanosis and coldness of the extremities is sometimes present. Auricular fibrillation is not uncommon.

The apex beat is small or absent. The heart sounds tend to be soft but a cadence of three sounds is usually heard. The additional sound occurs in early diastole and is rather shorter, higher pitched and earlier than the physiological third sound. It is related to the high pressure of ventricular filling.

Ascites is usually present and is a prominent feature of the disease. Its extent is in contrast to the smaller amount of peripheral oedema. Ascites is persistent and peritoneal tapping is followed by recurrence. The liver may be small or moderately enlarged, it is hard but cannot always be felt through the ascites. Pleural effusions of varying extent are often present. The disease runs a long chronic course with gradually increasing venous congestion, diminishing cardiac output and hepatic failure.

Radiology.—The heart is not enlarged and on radioscapy the pulsations are seen to be diminished and the angulations of the left border are smoothed out. The most conspicuous finding in many cases is extensive calcification of the pericardium. This is often best seen in oblique views and sometimes appears completely to encase the heart excepting the origin of the great vessels. Small pleural effusions are common. The lungs do not usually appear congested.

The electrocardiogram.—The P waves may show abnormal forms or they are absent when there is auricular fibrillation. The QRS complex tends to be of low voltage, but is otherwise normal. The S-T segment is isoelectric but T waves are usually flattened or inverted in several leads. Occasionally the electrocardiogram is surprisingly normal and there is some evidence that the pericarditis has not involved the underlying myocardium in such cases.

Other investigations are not usually indicated. Liver biopsy shows the degree of cirrhotic changes. Catheterisation of the right heart shows the high level of the right auricular venous pressure and the right ventricle shows a characteristic pressure

curve Diastolic filling causes a very rapid rise of pressure which then reaches a plateau presumably when the restrictive forces prevent further change

Diagnosis—The diagnostic features of constrictive pericarditis are jugular venous congestion, ascites and a quiet small heart with an additional heart sound in early diastole The radiological features are important and calcification of the pericardium is diagnostic in the presence of venous hypertension, however, there may be calcified plaques in the pericardium without pericardial constriction The electrocardiogram provides important additional evidence, but the diagnosis is essentially based on the clinical findings

Congestive heart failure is differentiated from constrictive pericarditis by the presence of extensive œdema, lower levels of jugular venous pressure, cardiac enlargement and the recognition of a cause for the heart failure Other causes of ascites are not usually difficult to differentiate because of the absence of severe venous congestion

The greatest problem in differential diagnosis is provided by obscure conditions which primarily involve or infiltrate the myocardium and endocardium, *e.g.* myocarditis, amyloidosis and endocardial fibrosis (see p 889) The hæmodynamics are somewhat similar, for diastolic filling may be restricted and the heart pulsations diminished, but calcification does not occur and the QRS complex of the electrocardiogram usually shows evidence of myocardial involvement An inspection of the pericardium at operation may in the last resort be the diagnostic method of choice so that pericardectomy can be performed if constriction is present

Prognosis—Untreated patients with constrictive pericarditis steadily deteriorate, become bedridden and die of the long term effects of low cardiac output and hepatic failure Surgical treatment entirely alters the outlook and patients are now living reasonably active lives several years after operation

Treatment—Decompression of the heart by surgical removal of the pericardium is indicated It is advisable to reduce ascites before operation, and pre operative treatment with streptomycin or other appropriate antibiotics is indicated if there is any evidence of activity of the infection Thickened pericardium is gradually removed from the left ventricle, and increased movement of the underlying heart or herniation through the area of removal indicates that decompression is being effective It is often necessary to carry the decortication process over the right heart and the right auricle Hæmorrhage and infection are dangers, but in expert hands and with the use of antibiotics the mortality rate is less than 10 per cent An indifferent result from pericardectomy may mean that resection has not been sufficiently extensive The results of operation are extremely satisfactory and it should be advised in all cases of constrictive pericarditis

CHRONIC ADHESIVE PERICARDITIS

In this condition there are fibrous adhesions between the parietal layer of the pericardium and adjacent mediastinal structures, the chest wall, the pleura or the diaphragm Various symptoms and signs have been attributed to this condition but none is reliable and most are due to other changes such as chronic valve disease, cardiac enlargement or even true constrictive pericarditis Although much has been written on this condition in the past, there is no evidence that it has any adverse effect on the function of the heart No treatment is indicated

PNEUMOPERICARDIUM

Air in the pericardial sac is a rare condition and occurs as a result of chest wounds and erosion by malignant growths from the bronchus or œsophagus It is invariably associated with serous or purulent effusion The symptoms and signs depend on

the presence or otherwise of cardiac tamponade its rate of development and the nature of the causal condition. Diagnosis is essentially radiological. Treatment depends on the cause, but severe tamponade requires relief by paracentesis of the sac.

HYDROPERICARDIUM

Transudation of excess fluid in the pericardium occurs in cardiac failure renal disease myxœdema and malignant hypertension. It is of entirely secondary importance and no special management or treatment is indicated other than for the causal disease.

TRAUMATIC PERICARDITIS

Hæmopericardium may result from stab wounds and various missiles which have not caused fatality by complete penetration of the heart. Cardiac tamponade tends to develop and indicates surgical evacuation of blood clot and repair of the wound. Foreign bodies lodging in tissues adjacent to the pericardium may lead to a recurrent sterile fibrinous pericarditis. Non penetrating injuries to the præcordium may lead to contusion of the heart with the development of a transient pericarditis detected by a friction rub and electrocardiographic signs of pericarditis. No treatment other than rest until signs and symptoms have disappeared is necessary (see Traumatic Heart Disease).

DISEASES OF THE ENDOCARDIUM

Pathological conditions which affect the mural and valvular endocardium are not necessarily due to inflammation. The pathological processes often show concurrent destruction and healing, there is a tendency to organisation whilst inflammatory reaction and local thrombus formation cause warty excrescences (vegetations) and at the same time ulceration. Lesions may be general or local and are often confined to valves (valvulitis). The process is acute or chronic and due to bacterial or non bacterial agents some known and other unknown. There is no satisfactory classification. The commonest form of endocarditis is rheumatic but this is inseparable from the whole picture of rheumatic carditis (see Rheumatic Fever, p. 48 and below).

SUBACUTE BACTERIAL ENDOCARDITIS

Ætiology.—Infection invariably occurs on a heart which is already damaged. The infecting organism is an alpha-hæmolytic streptococcus (viridans) in about 80 per cent. of cases; non-hæmolytic streptococci occur in about 5 per cent. and a variety of organisms including the hæmophilus and brucella groups occur in the remainder. The route and mode of infection is not definitely known, but subacute bacterial endocarditis not infrequently develops in patients with heart disease after the extraction of a septic tooth, tonsillectomy and after other relatively minor operations. A transient bacteræmia frequently follows such procedures and bacteria presumably settle on the damaged endocardium at this time. Bacterial endocarditis is especially associated with certain types of heart disease. (1) Rheumatic heart disease is present in more than half of the cases. Occasionally bacterial endocarditis develops in the presence of active rheumatism, but this is rare. Bacterial endocarditis does not usually develop on the grossly damaged rheumatic heart; it rarely occurs on the severely stenosed mitral valve and for this reason is almost never associated with auricular fibrillation; it commonly occurs in organic mitral incompetence and in aortic valve disease. (2) Patients with congenital heart disease are commonly affected, but here also bacterial endocarditis shows a strange predilection for certain abnormalities and never occurs in others. Patent ductus arteriosus, coarctation of the aorta, bicuspid aortic valve and ventricular septal defect are sometimes infected; it is perhaps significant that these lesions are in the high pressure and arterialised blood streams. Fallot's tetralogy and other lesions with right to left shunts are rarely affected and auricular septal defects are immune. (3) The aortic valves are occasionally affected in syphilitic aortitis and (4) an atherosclerotic aortic valve ring rarely appears to be the site of infection.

The sexes are equally affected. The majority of cases occur between 15 and 35 years of age. Bacterial endocarditis is extremely rare in infancy and childhood, but it is not uncommon in elderly patients.

Pathology.—The primary lesions of bacterial endocarditis are in the heart; the secondary ones are due to peripheral arterial emboli, toxæmia and heart failure.

In the heart the lesions are proliferative and destructive. Small friable vegetations form at the site of endocarditis. They tend to form at the contact margins of valves, but may spread over the whole valve and extend to the adjacent mural endocardium. Ulceration may occur and rupture of valve cusps and chordæ is not uncommon. Microscopically the vegetations surmount the endocardium and the valve beneath may show only a moderate cellular reaction. The vegetations consist of a more or less compact mass of platelets and fibrin which enmesh clumps of organisms.

The heart lesions are mainly valvular but the sites of congenital anomalies are also affected, e.g. the patent ductus and the interventricular septum. Myocarditis and pericarditis are not important features compared with the endocardial lesions. The myocardium shows accumulations of cells (Bracht-Wächter bodies) but it is not apparently as severely affected as in rheumatic carditis. Pericarditis may occur but is rare.

Arterial emboli may produce infarction of varying degrees in the kidney, spleen, brain, retina and gut, and gangrene of distal portions of the limbs; when the right heart is affected, pulmonary infarction may occur. Bacterial embolisation of medium-sized arteries may produce a local arteritis with mycotic aneurysm formation; there is local medial necrosis and bulging of the damaged vessel. The kidney is almost invariably affected and shows three types of lesion; (1) large wedge infarctions from embolic occlusion of medium-sized vessels; (2) focal glomerulo-nephritis in which a varying number of glomeruli show an occluded vessel with surrounding reaction and organisation; the surface of the kidney shows petechial spots and has been

called the "flea bitten kidney" (deriving from the days when flea bites were "physiological" and did not cause a brisk surrounding allergic response), (3) a diffuse glomerulo nephritis is not uncommon and has been found in patients dying after penicillin treatment has cured the active endocarditis. Heart failure is not a prominent feature until late in the disease.

Clinical Features—The symptoms and signs are due to toxæmia, septicæmia, emboli in various organs and cardiac failure. The onset is gradual so that it is rarely possible to determine accurately when the disease began, but occasionally the onset is sudden, with high fever and rigors. The initial symptoms are general weakness and anorexia, with frequent sweats. Fever is usual and variable, there may be brief apyrexial periods, but it is mostly continuous and rarely rises above 102° F. Rigors are not uncommon and occur especially when there are crops of petechial hæmorrhages. Headache and pain in the joints and limbs are common. Anæmia develops from the start and tends to be progressive, splenomegaly appears early in the disease.

The heart—In the great majority of cases there are definite signs of heart disease at the onset. Often the signs are slight at first, a pansystolic murmur at the apex with no cardiac enlargement indicating a minimal mitral valve lesion is common. On the other hand, there may be obvious signs of extensive aortic valve disease or the signs of a congenital defect. As the disease progresses it is common to find evidence of spread to other valves, especially the aortic valve when the mitral valve was originally involved. Undue importance has been attached to changes in the character of murmurs from day to day. The sudden appearance of a loud rasping or a musical murmur in systole or diastole may be due to the rupture of a cusp or fracture of one of the chordæ tendinæ. Auricular fibrillation is most unusual in the early stages of the disease, but it occasionally develops later.

Embolic phenomena—Arterial emboli cause important signs of the disease. Lesions range from multiple microscopic ones to single large ones and may affect any organ of the body. The skin shows a variety of lesions. Petechiæ are commonest, there may be no more than two or three or there may be vast numbers, they are commonly seen under the nails as splinter hæmorrhages at the base of the nail, in the conjunctiva of the lower lid, and in the fundus oculi and the buccal mucosa. Petechiæ may recur in showers, but in the early stages a diligent search is often required to find one. Larger areas of ecchymosis are not uncommon and may be tender. Osler's nodes are small, tender, swollen areas, usually a few millimetres in diameter, occurring commonly on the pulp of the fingers or toes, they are usually discoloured and transient. The patient complains of a sudden tender spot and often the examiner finds no signs a few days later. Osler's nodes appear to be almost specific for the disease.

The spleen enlarges early in the disease and is generally rather soft. Episodes of sudden severe left hypochondriac pain suggest splenic infarction, the spleen is then tender and a friction rub due to perisplenitis may be heard. Sudden loin pain may indicate renal infarction which sometimes causes macroscopic hæmaturia. Microscopic hæmaturia is common and is the result of focal embolic nephritis. Renal failure is a late manifestation of the disease.

Cerebral embolic episodes with resulting hemiplegia are not uncommon. Rarely diffuse cerebral damage may produce a meningitic or encephalitic picture. Central retinal arterial embolism occasionally occurs and causes sudden blindness and optic atrophy may cause a more insidious loss of vision. The mesenteric vessels and those of the limbs are frequently involved. Mycotic aneurysm may develop, leading to fatal hæmorrhage or gangrene. Sudden pain in a joint is probably due to endarterial embolism, repeated attacks of joint pain may cause confusion with rheumatic fever. Coronary embolism may cause cardiac infarction, resulting in heart failure or sudden death.

When bacterial endocarditis complicates a congenital lesion with left to right shunt, e.g. patent ductus arteriosus and ventricular septal defect there may be few

if any, manifestations of systemic embolisation, the clinical features are then largely pulmonary, the lungs may show repeated infarction and rarely abscess formations

Cachexia with a *cafe au lait* complexion, gross finger clubbing, severe anaemia, hæmorrhagic lesions, heart failure and renal failure are late features of the disease. The clinical picture and natural history of bacterial endocarditis have been changed by antibiotic drugs and chemotherapy. In early cases the disease may be completely cured, however, this is by no means invariably the case. When treatment is started late in the disease infection may be eradicated, but extensive valve lesions may lead to progressive heart failure. In some cases progressive renal failure from diffuse nephritis continues after sterilisation of the infection.

Investigations—The blood shows a progressive anaemia averaging between 8 and 12 g of hæmoglobin per 100 ml, the red cells rarely fall below three million per c mm. The white cell count is variable, most cases show a slight to moderate leucocytosis but leucopenia sometimes occurs. Large monocytes are usually increased. The sedimentation rate is usually raised but this is not invariable.

Blood cultures are positive in some 75 per cent of cases. Several samples of 10 to 20 ml of blood should be examined, and several days must elapse before culture can be accepted as negative. When cultures are attempted after penicillin therapy has started they are likely to be negative unless treated with penicillinase.

Radiological and electrocardiographic examinations aid the assessment of the cardiac condition but are not specifically altered by bacterial endocarditis.

Diagnosis—Early diagnosis is imperative if antibiotic therapy is to prevent further irreparable damage to the heart. Any patient with an organic heart murmur who has vague ill health or prolonged fever should at once be considered as a possible case of bacterial endocarditis and appropriate investigations undertaken. The main features which lead to clinical diagnosis are (1) heart disease, (2) fever, (3) embolic features, particularly petechiae and Osler's nodes, (4) splenomegaly, (5) anaemia and (6) hæmaturia. Positive blood cultures confirm the diagnosis but in some 10 to 15 per cent of cases the blood culture remains negative. The diagnosis is rarely tenable when the hæmoglobin concentration and the sedimentation rate are normal. **Differential diagnosis**—If bacterial endocarditis is kept in mind when considering patients with an organic heart murmur, confusion with other conditions rarely arises. However, bacterial endocarditis which is characterised by prolonged fever and the involvement of many organs must obviously be distinguished from many other conditions.

Fever, endocarditis and anaemia due to active rheumatism in adolescents and young adults may resemble bacterial endocarditis, and in any case these conditions may coexist. The presence of Osler's nodes, petechiae, clubbing, splenomegaly and positive blood cultures do not therefore exclude rheumatic fever but indicate the existence of bacterial infection. Other causes of fever such as malignant reticulosis, tuberculosis and the enteric fevers should be considered but are readily excluded by the absence of signs of endocarditis described above. Malignant reticulosis with fever, splenomegaly and anaemia may cause difficulty but investigations usually reveal the true nature of the condition and signs of endocarditis are absent. Tuberculosis and the enteric fevers causing pyrexia and wasting are usually excluded on clinical grounds, but in cases of doubt the blood culture, Widal reaction, Mantoux test and a search for tubercle bacilli are decisive. Disseminated lupus erythematosus and other collagen diseases, if associated with a heart murmur may resemble bacterial endocarditis, but clubbing, Osler's nodes and positive blood cultures are absent, and in disseminated lupus erythematosus the presence of L.E. cells can be demonstrated in the blood (see p 933). If the presenting feature of bacterial endocarditis is due to embolism, such as hemiplegia, hæmaturia, pulmonary infarction, the nature of the underlying disease may not be immediately apparent but continued fever and other features soon reveal the presence of infection and endocarditis.

Infected ventricular septal defect causing repeated episodes of pulmonary infection and infarction may be confusing but if the possibility of superadded endocarditis is always kept in mind when dealing with patients with an organic murmur the diagnosis is readily made

Prognosis—Prognosis without treatment is hopeless. Antibiotic therapy has completely changed the outlook which is now good, provided that treatment is applied early in the disease. Relapse may occur and when this happens it usually does so within one month of the cessation of treatment. Resistant strains of organisms may develop, but by increasing dosage and with the wide range of antibiotics now available this problem can be overcome. In spite of sterilisation of the infection some cases continue to deteriorate from heart failure, renal failure, or as the result of infarction of vital organs. Heart failure is the commonest cause of death, and tends to occur during treatment or within 6 months after treatment. Other adverse prognostic factors are increasing age, severe primary valve lesions and poor nutrition of the patient, the most important factor in prognosis is the duration of infection prior to the start of treatment.

Treatment—**PROPHYLACTIC**—Any patient with rheumatic heart disease (especially organic mitral incompetence, or lone aortic valve disease) or with congenital heart disease should receive penicillin before undergoing any operative procedure particularly dental extraction tonsillectomy or any sort of endoscopy. 500 000 units of soluble penicillin should be given 1 hour before operation and the blood level maintained for 48 hours thereafter by a 12 hourly injection of 250 000 units procaine penicillin. Larger doses for a longer period before or after operation are indicated if this is for a known septic lesion.

CURATIVE—Bed rest, a good diet and added iron are indicated but the essential part of treatment is the early and adequate administration of penicillin. The sooner it is started the better is the outlook, and a delay of 24 hours may determine the existence of a serious embolic episode. If the clinical diagnosis is reasonably certain penicillin therapy should be started after several samples of blood have been withdrawn for culture during the first 24 to 48 hours. There is no justification for awaiting a positive culture which may take several days, and indeed negative culture does not invalidate a sound clinical diagnosis. The positive blood culture provides confirmation of the diagnosis, and the infecting organism should be tested for sensitivity to penicillin and other antibiotics. Penicillin should be given in a minimum daily dose of 2 000 000 units for 6 weeks. It should be divided into a 4 hourly intramuscular injection or given by continuous intravenous drip. It is probable that 12 hourly injections of 1 000 000 units of procaine penicillin are adequate for 90 per cent of cases however the intermittent intramuscular route of soluble penicillin is recommended at least until the results of bacteriological investigation are available. A larger daily dose should be given if the resistance of the infecting organism is four or more times that of the Oxford staphylococcus or if clinical improvement is not apparent in the first week. On such grounds it may be necessary to give 6 000 000 units or occasionally 10 000 000 units daily. In other cases depending on the bacteriology and clinical response it may be advisable to combine penicillin with streptomycin or other antibiotic drugs.

The effectiveness of treatment is shown by remission of fever, improved appetite and well being and a gain in weight, anaemia improves and the sedimentation rate falls. It should be noted that petechiae may continue to appear for some time after the temperature is normal. Failures of treatment are due to delay in starting treatment through delay in diagnosis, inadequate dosage and the development of resistant organisms.

SURGICAL TREATMENT—In cases of patent ductus arteriosus it is advisable to ligate the ductus when treatment and convalescence are completed. Occasionally ligation should be advised whilst infection is still present if this is resistant to anti-

biotic therapy. Mycotic aneurysms require removal and grafting of the affected vessel where this is possible.

Ninety per cent. of patients with bacterial endocarditis may be cured if treated within 6 weeks of the onset of the disease, but if treatment is delayed until after the third month, only 50 per cent. are cured.

ACUTE BACTERIAL ENDOCARDITIS

There is much overlap with subacute bacterial endocarditis and now that serious septic conditions are treated effectively with antibiotic drugs, the differentiation of these conditions is of doubtful value.

Acute bacterial endocarditis is now rare. It is mostly due to one of the pyogenic organisms, and is incidental to the course of an acute pyogenic illness. The primary lesion is generally obvious, such as suppurative pneumonia, puerperal fever, osteomyelitis, a carbuncle or gonorrhœa. An undamaged heart may rarely be affected. Vegetations develop on the valvular and mural endocardium, and there is a greater tendency to ulceration and destruction than in subacute bacterial endocarditis.

Clinical Features.—The onset is rapid, but it cannot always be detected against the background of the severe septic primary disease. The symptoms are largely septicæmic; swinging fever, rigors and sweats are usual; pain and swelling of joints together with cutaneous ecchymoses are common. Finger clubbing is rare, but petechial hæmorrhages and a soft enlargement of the spleen are usual. Embolic phenomena occur as in the subacute variety, but tend to produce metastatic abscesses. Meningitis, pericarditis, pleurisy and peritonitis are possible complications.

Prognosis.—This disease was invariably fatal in a few days or weeks, but treatment of the ætiological condition with antibiotic drugs is preventative, and curative if the endocarditis has not progressed too far (see Subacute Bacterial Endocarditis).

Treatment.—Treatment is essentially that of the primary condition and otherwise the same as for subacute bacterial endocarditis (see p. 885).

endocarditis).—Endocardial vegetations are sometimes found in this rare condition. The valves are not affected so that heart murmurs are not a prominent feature. The vegetations are large and fleshy but do not appear to fragment, for embolism is uncommon (see p. 933).

Tuberculosis of the endocardium is extremely rare. *Granulomatous verrucae* and ulcers due to tubercle have been described. *Non-bacterial mural thromboses* are not uncommonly found at necropsy after prolonged cachectic illnesses such as nephritis, carcinomatosis and chronic pulmonary suppuration. These lesions develop in the terminal stage of these illnesses and are non-specific platelet agglutinations on the mural endocardium.

DISEASES OF THE MYOCARDIUM

All forms of heart disease eventually affect the heart muscle and in some, such as coronary disease and rheumatic fever, the myocardium is directly damaged from the onset by ischaemia or inflammation. This section deals with those relatively rare conditions in which the myocardium seems to be affected primarily by inflammation, infiltration and metabolic disturbances.

MYOCARDITIS

In the past this term has been misused. It should be applied only to conditions in which the myocardium is affected by inflammatory processes. Classification is unsatisfactory because the aetiology of myocarditis is obscure. Diagnosis is often difficult because signs and symptoms are sometimes slight or absent, and circulatory impairment may be due to vasomotor disturbances resulting from a primary disease rather than from myocarditis.

Aetiology and Pathology.—Rheumatic fever is the most important cause of myocarditis in Great Britain. The lesions are essentially interstitial and consist of either widespread or focal accumulation of cells and oedema; it is part of a total carditis (see below and Rheumatic Fever, p. 48). Bacterial endocarditis (see p. 885) also causes myocarditis which may be responsible for heart failure; the lesions are both parenchymal and interstitial with small focal accumulations of cells which may form a suppurative myocarditis in the pyogenic varieties. Some degree of myocarditis probably occurs in many specific bacterial, viral and rickettsial diseases, but it is not usually recognised and rarely causes significant deterioration apart from the fact that myocarditis occurs in the more serious cases of the particular infection. Diphtheria is an exception; its faucial, laryngeal or cutaneous forms frequently produce serious parenchymatous myocarditis which is not necessarily related to the severity of infection at the primary site (see below). The cause or causes of isolated interstitial myocarditis are unknown (see below, p. 891).

Clinical Features.—The clinical picture depends on the severity of the myocardial lesion and on its cause. Myocarditis leads to a diminished cardiac reserve and to dilatation of the heart with congestive cardiac failure when muscle damage is extensive and severe. Fever, malaise and other general symptoms depend largely on the aetiology. A dull praecordial ache is common but may be absent, or variable—it is more often present in interstitial myocarditis than in the toxic parenchymal lesions which do not usually involve the pericardium. Dyspnoea is usual but often not a prominent feature and it may be impossible to distinguish cardiac dyspnoea from that due to an associated pneumonitis, e.g. in pneumonia, typhoid and rickettsial disease. It is a most significant symptom in diphtheria.

Examination usually shows a tachycardia which is greater than expected from

the fever. The pulse tends to be soft and thready, and the blood pressure is normal or low with a tendency to low pulse pressures. Pulsus alternans may be present, extrasystoles are common and the more serious arrhythmias sometimes develop. The apex beat is diminished in force and may be shifted to the left from cardiac enlargement. The heart sounds tend to become soft and triple rhythm is usually present due to a third heart sound. Murmurs are often conspicuously absent but with increasing dilatation and the development of heart failure, mitral and tricuspid systolic murmurs tend to develop.

All degrees of heart failure may result from myocarditis, but acute left heart failure is rare. Congestive heart failure, shown by a rise in jugular venous pressure, may occur early in the disease and may be progressive or transient, depending on aetiology. In diphtheria the great veins may be collapsed when shock is associated with heart failure, this is usually a fatal combination.

Radiology—Radiographic examination reveals the extent of cardiac enlargement and shows the presence of pulmonary congestion which, however, is not usually a prominent feature of myocarditis. In diphtheritic carditis and other acute cases with evidence of heart failure, examination should not be carried out except by means of portable apparatus at the bedside.

The **electrocardiogram** provides important evidence of myocardial disease and is pathological in almost all cases of myocarditis. Changes in the QRS complex are variable, the voltage may be diminished with notching of complexes and even intraventricular delay shown by widening of the QRS. The S-T segment and T waves are most frequently affected. The S-T tends to be depressed and T waves are flat or inverted in several leads. As in pericarditis the emphasis is on the widespread nature of relatively slight changes compared with the more localised and severe changes which are found in cardiac infarction. Arrhythmias and conduction defects are not uncommon.

TYPES OF MYOCARDITIS—1 *Diphtheritic myocarditis*—Some degree of myocarditis probably occurs in the majority of patients with diphtheria. The muscle fibres are diffusely damaged and histological examination may show little in contrast to the findings in interstitial myocarditis. In some it produces serious clinical features and may be fatal. Where recovery occurs it is usually complete, but occasionally there are permanent electrocardiographic changes. The first clinical signs tend to appear in 7 to 10 days. Arrhythmias occur early and heart block is common. Other signs of myocarditis may develop and are followed by those of congestive heart failure in severe cases. The haemodynamic state may be complicated by toxic depression of the vasomotor system so that the shock state is associated with central failure.

Prognosis—The outlook for diphtheritic carditis which is causing symptoms and signs is poor, but if there is recovery from the acute illness it is usually complete.

Treatment—Prophylaxis is essential and consists of the early diagnosis and treatment of diphtheria with adequate antitoxin and bed rest for 1 month. There is no active curative treatment for carditis when this has developed. Patients should be kept at complete rest for at least 6 weeks. If there is congestive heart failure a mercurial diuretic should be given but digitalis is contraindicated.

2 *Rheumatic myocarditis* cannot be separated from the whole picture of rheumatic carditis which generally is dominated by endocarditis. The myocarditis is interstitial with Aschoff bodies in various stages of development scattered throughout the muscle, and particularly in the regions of the auriculo ventricular junctions. Myocarditis is always severe and probably responsible for the outcome in cases dying during the acute and subacute phases of the disease.

3 *Isolated myocarditis* (Fiedler's myocarditis, primary myocarditis, idiopathic myocarditis).

These unsatisfactory terms indicate that the cause of the disease is unknown and it may not be a single disease but rather a similar myocardial reaction to various

causes. However the pathological and clinical findings are fairly constant in the cases which have been described. At necropsy the heart is dilated and soft the pericardium and endocardium are normal. Histological examination of the myocardium shows a diffuse interstitial cellular reaction which is mainly monocytic but various other cells are found. There is a variable degree of damage to the muscle cells and usually some degree of healing by interstitial fibrosis.

The symptoms are slight at first with a dull sternal aching and fatigue. Soon congestive heart failure develops and deterioration continues in spite of treatment until death occurs in a few weeks from the onset. Thrombo embolic episodes are often a feature and there are phases of fever but much of the course may be afebrile. The signs are as in other cases of myocarditis and congestive heart failure. The electrocardiogram shows pathological changes suggesting myocarditis as described above. No specific tests for this disease are known. Isolated myocarditis must be differentiated from all causes of congestive heart failure and the diagnosis is largely made by exclusion of other disease and the positive signs described above. A rapidly deteriorating febrile course is strongly suggestive but confirmation comes only with necropsy. The treatment for congestive heart failure is indicated but lack of response is characteristic of the disease.

NON INFLAMMATORY DISEASE OF THE MYOCARDIUM — Amyloidosis of the heart — Primary amyloidosis of the myocardium is an uncommon condition but has been recognised many times during recent years. In this form of amyloidosis there is no associated chronic suppurative and the heart is mainly affected but amyloid may be found elsewhere e.g. in vessels of the tongue and gums. At necropsy the heart is dilated and the muscle feels firm but histological examination shows extensive replacement of the muscle cells by amyloid material. There are no symptoms or signs apart from those due to progressive heart failure and cardiac enlargement. The disease runs a long course often with signs of heart disease for 3 to 5 years. The electrocardiogram shows signs of extensive myocardial damage. Bundle branch block or pathological Q waves in several leads may occur. The electrocardiogram may be indistinguishable from the pattern of myocardial infarction but the changes tend to be more widespread in amyloidosis. Radiological examination shows cardiac enlargement. Histological examination from biopsy may show deposits of amyloid material in the walls of small vessels. There is no specific remedy but heart failure requires the usual treatment.

Idiopathic hypertrophy of the heart — The conditions to which this descriptive term applies do not form a single aetiological group. The essential feature is the absence of any known cause of hypertrophy. Massive hearts are occasionally responsible for heart failure in infants and children the condition has been called congenital idiopathic hypertrophy but there is little evidence that it is a congenital abnormality.

Familial cardiomegaly mostly affects young adults. There is great cardiac enlargement and the electrocardiogram often shows bundle branch block. Death is often sudden or may follow progressive heart failure. Cardiomegaly together with myocardial infiltration and degeneration occurs in Friedreich's disease and in myotonia atrophica. Arrhythmias and various degrees of heart block are not uncommon in these neurological conditions and occasional cases have led to heart failure or sudden death.

The myocardium may be affected in *scleroderma* by a similar process to that which is found in the skin. Cardiovascular symptoms and electrocardiographic changes occur. Sarcoid infiltration of the heart may occur in generalised *sarcoidosis* it is extremely rare.

Von Gierke's Disease — This condition is due to a congenital error of metabolism resulting in abnormal glycogen storage. Both sexes are affected and the condition may be familial. Abnormal glycogen storage occurs in various organs including the

liver, kidneys and the heart. Involvement of the heart causes cardiomegaly and sudden death may occur. Diagnosis is suggested by the combination of unexplained cardiomegaly and hepatomegaly. No treatment is known.

W. W. BRIGDEN

CONGENITAL HEART DISEASE

About three children in each thousand are born with congenital heart disease, but those with the more serious forms do not live long, and by 10 years of age the proportion is reduced to about one in each thousand. In about 2 per cent. of all patients with organic heart disease, the condition is congenital.

Ætiology.—The cause is nearly always a failure of development. In the past some types have been attributed to fetal endocarditis but this is almost certainly incorrect. Rubella during the second month of the mother's pregnancy is an uncommon cause and some other virus infections may act in the same way.

It seems, however, that heredity is the main cause. Rarely, but more often than would be expected by chance, parent and child or two sibs both have congenital heart disease. Generally the subject is the only known sufferer in the immediate family but statistics show that sibs and relatives are affected more often than the general population. Most other congenital abnormalities are found from time to time in association.

Lesions of the aortic valve and coarctation of the aorta are found more often in boys; patent ductus arteriosus and atrial septal defect are more common in girls.

Diagnosis and Classification.—Diagnosis has become more important with the progress of surgical treatment. Several forms of congenital heart disease, including those of most practical importance, can be diagnosed by simple clinical methods alone; others may be difficult and may require cardiac catheterisation or angiocardigraphy.

Increased understanding of some underlying principles has made classification more rational and comprehensible. The division into those with and those without central cyanosis is most important and if the cyanosis is only occasional or doubtful the patient must be kept under observation until it is decided.

Central cyanosis is best recognised in the tongue and mucous membrane of the mouth, in the conjunctivæ and in the nails *when the hands are warm*. The arterial oxygen may be as low as 50 to 60 per cent., and is generally under 90 per cent. when central cyanosis is obvious. Peripheral cyanosis may be very striking in the hands, cheeks, ears and lips, and is seen in Raynaud's syndrome, in many open-air workers, and in any thin child after exposure on a cold day. The arterial oxygen saturation is normal and it has little significance for diagnosis. It may be due to peripheral stasis only or more rarely to a general slowing of the circulation.

Central cyanosis nearly always indicates a right-to-left (veno-arterial) shunt and therefore gives a partial diagnosis at once. There must be an opening between the right and left sides of the heart and there must be something else raising the pressure on the right side so that the shunt is from right to left.

A second division is into those where the blood flow to the lungs is increased (pleonæmic) and those where it is diminished (oligæmic). This is of great practical importance, especially for cyanotic cases, since it can now be increased by operation. The distinction is made mainly by the appearances of the radiogram and by radioscopy, but a loud or widely split pulmonary second sound will suggest pulmonary hypertension or an increased pulmonary flow.

Oligæmic lungs are shown by light vascular markings in the lung fields. They are most common in the cyanotic group. Pleonæmic lungs are shown by large pulmonary arteries and increased vascular markings, often with pulsation that can be easily seen in the pulmonary branches.

Pleonæmic lungs indicate a left-to-right (arterio-venous) shunt and so give part of the diagnosis at once. Atrial septal defect, ventricular septal defect and patent ductus arteriosus (all acyanotic) and transposition (cyanotic) are the main examples, and all these may give a somewhat similar radiological picture. If the amount passing through the shunt is small the changes in the lung fields may not be apparent.

Congenital heart disease can, therefore, be divided into the four following groups
 i Acyanotic With no communication between the two sides of the heart ii Acyanotic With a potential communication between the two sides (*i.e.* a foramen ovale that is not sealed) iii Acyanotic With a left-to-right (arterio-venous) shunt and pleonæmic lungs iv Cyanotic With a right-to-left (veno-arterial) shunt most of these have oligæmic lungs but some have pleonæmic lungs because there is also a left to right shunt

General Principles of Treatment—Even if an exact diagnosis is uncertain most patients can be given reasonable advice about the degree of activity that is best for them and about the prognosis. Symptoms are generally more important than physical signs in judging this, although there may be a large heart with relatively few symptoms. A patient with striking physical signs may have little disability.

The best plan is to find what the child can do by gradually increasing its activity and then to keep the daily level somewhat below this and to insist on adequate rest and a long night in bed. This principle applies in the same way to the cyanotic children, even if they can do very little. In other respects they should be treated as far as possible as normal children. Some patients are still limited in their activity more than they should be because a systolic murmur has been heard, and improvement may simply mean that a child has broken free from unnecessary restrictions and is doing as much as he can without distress.

The child should be carefully treated when transient infections occur and sulphonamides and antibiotics should be used readily to minimise the risks of bacterial endocarditis, as nearly all forms except atrial septal defect are specially liable to this infection.

(1) ACYANOTIC WITH NO COMMUNICATION BETWEEN THE LEFT AND RIGHT SIDES OF THE HEART

Ectopia cordis—The heart is situated outside the thoracic cavity and the patient is not likely to survive for long. Simpler defects of the pericardial sac are also found.

Dextrocardia—When the heart is on the right side of the chest with complete transposition of all the viscera they form a mirror image of the normal. This has no clinical significance except that there is sometimes bronchiectasis. It must be distinguished from a heart displaced to the right by intrathoracic disease. It is inherited as a Mendelian recessive character and so is more common in the offspring of first-cousin marriages.

Less commonly the heart is on the right without the abdominal and other viscera being transposed, or the heart is on the left with the abdominal viscera transposed. It is then difficult for the circulation to function, for blood from the venæ cavae will tend to enter the wrong atrium. There are nearly always other congenital abnormalities of the heart, large septal defects and perhaps pulmonary stenosis and transposition of the aorta and pulmonary trunk, and the patient is generally cyanotic.

Congenital heart block—This is not very uncommon. Although the block is nearly always complete, the rate is faster than in most other forms, about 50 a minute or more after exertion. Stokes-Adams attacks are rare, and generally the prognosis is good. It is often associated with a small ventricular septal defect.

Bicuspid aortic valves—These are not uncommon but generally cannot be recognised as they do not cause aortic regurgitation unless they become deformed by disease. Atheroma may occur early, and they are specially prone to bacterial endocarditis, so that the diagnosis may be suspected when this occurs on the aortic valves only in a patient without a rheumatic history.

Aortic stenosis.—Generally this is valvular but sometimes it is sub-valvular and due to a failure of development of the bulbus cordis. If there is a rough systolic murmur and thrill maximal in the aortic area in a child with few symptoms and a heart that is normal in size, the stenosis is more likely to be congenital than rheumatic, as the latter generally occurs with a seriously damaged heart. The slow-rising pulse and small pulse pressure are later signs of more severe stenosis. Many patients do well, and in the absence of cardiac enlargement, electrocardiographic signs of left ventricular strain, or other special features, it should call for little, if any, limitation of activity. Later, however, perhaps in the fourth decade, increasing fibrosis and calcification of the valve are likely to make the stenosis worse.

Coarctation of the aorta.—The aorta is narrowed so that the pressure on the proximal side is raised to overcome the obstruction. The narrowing varies in degree, and in severe cases there may be an hour-glass stenosis. The site of the coarctation is not just above the valve but farther round the arch at the isthmus where the ductus arteriosus joins the aorta, so that the left subclavian is above the constriction. A much lower pressure in the left than in the right arm would indicate obstruction above the origin of the left subclavian artery.

The auscultatory signs are similar to those of aortic stenosis, but may be slight. Sometimes the systolic murmur may be widespread and heard also over the back as it may be produced over dilated collateral arteries. The essential diagnostic feature is the high pressure in the upper part of the body with a low pressure and a delayed or absent pulse in the arteries of the legs; and if it is made an invariable rule to feel for the femoral pulse in all patients with a high brachial blood pressure, with unexplained aortic incompetence, or with abnormal pulsation in the neck, the diagnosis should not be missed. Dilated collateral vessels may be found over the chest or back, especially round the scapula, and these are often made more obvious if the patient bends forward with his arms hanging by his side. Notching of the lower border of the ribs on radiographs may be further confirmation, but the diagnosis should be made without this.

The prognosis is good in patients without symptoms where the lesion is found by chance after the age of 20, and not so good in those where symptoms develop in childhood, though slight dyspnoea or aching of the legs are hardly significant. The blood pressure does not rise progressively through life, though it may not reach its maximum till 15 or 20 years of age. A patient with a pressure of 180 mm. may show only slight left ventricular enlargement and may be able to lead an active life for many years.

Aortic incompetence is common and may be due to dilatation of the aorta or to changes in the aortic valves and may cause some of the symptoms. Congenital cerebral aneurysms are often present and may lead to fatal subarachnoid hæmorrhage, and though the risk of this is minimised by reduction of the blood pressure it is not entirely removed.

The condition can now be cured by operation but it is difficult to decide when it is indicated, as the prognosis is often good. Operation should be performed only by those with special experience, and even in such hands, the mortality is about 10 per cent., though this may continue to drop. If the patient has serious symptoms in childhood or if the blood pressure continues to rise much after 15 years of age, operation should be advised. After 20, the risks are greater and the anastomosis may be difficult or impossible, so that a greater degree of disability is needed to justify the risk.

(2) **ACYANOTIC. WITH A POTENTIAL COMMUNICATION BETWEEN THE TWO SIDES OF THE HEART (Cyanose tardive).**

Pulmonary valvular stenosis is often found with a closed ventricular septum as well as with Fallot's tetralogy (see p. 897). The stenosis may not be severe in spite of striking physical signs—a rough systolic murmur and thrill, maximal in the pulmonary area and sometimes a diminished and single second sound at this site—and

Pleonaemic lungs indicate a left to right (arterio venous) shunt and so give part of the diagnosis at once. Atrial septal defect, ventricular septal defect and patent ductus arteriosus (all acyanotic) and transposition (cyanotic) are the main examples and all these may give a somewhat similar radiological picture. If the amount passing through the shunt is small the changes in the lung fields may not be apparent.

Congenital heart disease can therefore be divided into the four following groups:
 i. Acyanotic. With no communication between the two sides of the heart.
 ii. Acyanotic. With a potential communication between the two sides (i.e. a foramen ovale that is not sealed).
 iii. Acyanotic. With a left to right (arterio venous) shunt and pleonaemic lungs.
 iv. Cyanotic. With a right to left (veno arterial) shunt.
 Most of these have oligæmic lungs but some have pleonaemic lungs because there is also a left to right shunt.

General Principles of Treatment—Even if an exact diagnosis is uncertain most patients can be given reasonable advice about the degree of activity that is best for them and about the prognosis. Symptoms are generally more important than physical signs in judging this although there may be a large heart with relatively few symptoms. A patient with striking physical signs may have little disability.

The best plan is to find what the child can do by gradually increasing its activity and then to keep the daily level somewhat below this and to insist on adequate rest and a long night in bed. This principle applies in the same way to the cyanotic children even if they can do very little. In other respects they should be treated as far as possible as normal children. Some patients are still limited in their activity more than they should be because a systolic murmur has been heard and improvement may simply mean that a child has broken free from unnecessary restrictions and is doing as much as he can without distress.

The child should be carefully treated when transient infections occur and sulphonamides and antibiotics should be used readily to minimise the risks of bacterial endocarditis as nearly all forms except atrial septal defect are specially liable to this infection.

(1) ACYANOTIC WITH NO COMMUNICATION BETWEEN THE LEFT AND RIGHT SIDES OF THE HEART

Ectopia cordis—The heart is situated outside the thoracic cavity and the patient is not likely to survive for long. Simpler defects of the pericardial sac are also found.

Dextrocardia—When the heart is on the right side of the chest with complete transposition of all the viscera they form a mirror image of the normal. This has no clinical significance except that there is sometimes bronchiectasis. It must be distinguished from a heart displaced to the right by intrathoracic disease. It is inherited as a Mendelian recessive character and so is more common in the offspring of first cousin marriages.

Less commonly the heart is on the right without the abdominal and other viscera being transposed or the heart is on the left with the abdominal viscera transposed. It is then difficult for the circulation to function for blood from the venæ cavae will tend to enter the wrong atrium. There are nearly always other congenital abnormalities of the heart: large septal defects and perhaps pulmonary stenosis and transposition of the aorta and pulmonary trunk and the patient is generally cyanotic.

Congenital heart block—This is not very uncommon. Although the block is nearly always complete the rate is faster than in most other forms about 50 a minute or more after exertion. Stokes Adams attacks are rare and generally the prognosis is good. It is often associated with a small ventricular septal defect.

Bicuspid aortic valves—These are not uncommon but generally cannot be recognised as they do not cause aortic regurgitation unless they become deformed by disease. Atheroma may occur early and they are specially prone to bacterial endocarditis so that the diagnosis may be suspected when this occurs on the aortic valves only in a patient without a rheumatic history.

Aortic stenosis—Generally this is valvular but sometimes it is sub valvular and due to a failure of development of the bulbus cordis. If there is a rough systolic murmur and thrill maximal in the aortic area in a child with few symptoms and a heart that is normal in size, the stenosis is more likely to be congenital than rheumatic, as the latter generally occurs with a seriously damaged heart. The slow-rising pulse and small pulse pressure are later signs of more severe stenosis. Many patients do well, and in the absence of cardiac enlargement, electrocardiographic signs of left ventricular strain, or other special features, it should call for little, if any, limitation of activity. Later, however, perhaps in the fourth decade, increasing fibrosis and calcification of the valve are likely to make the stenosis worse.

Coarctation of the aorta—The aorta is narrowed so that the pressure on the proximal side is raised to overcome the obstruction. The narrowing varies in degree, and in severe cases there may be an hour glass stenosis. The site of the coarctation is not just above the valve but farther round the arch at the isthmus where the ductus arteriosus joins the aorta, so that the left subclavian is above the constriction. A much lower pressure in the left than in the right arm would indicate obstruction above the origin of the left subclavian artery.

The auscultatory signs are similar to those of aortic stenosis, but may be slight. Sometimes the systolic murmur may be widespread and heard also over the back as it may be produced over dilated collateral arteries. The essential diagnostic feature is the high pressure in the upper part of the body with a low pressure and a delayed or absent pulse in the arteries of the legs, and if it is made an invariable rule to feel for the femoral pulse in all patients with a high brachial blood pressure, with unexplained aortic incompetence, or with abnormal pulsation in the neck, the diagnosis should not be missed. Dilated collateral vessels may be found over the chest or back, especially round the scapula, and these are often made more obvious if the patient bends forward with his arms hanging by his side. Notching of the lower border of the ribs on radiographs may be further confirmation, but the diagnosis should be made without this.

The prognosis is good in patients without symptoms where the lesion is found by chance after the age of 20, and not so good in those where symptoms develop in childhood, though slight dyspnoea or aching of the legs are hardly significant. The blood pressure does not rise progressively through life, though it may not reach its maximum till 15 or 20 years of age. A patient with a pressure of 180 mm may show only slight left ventricular enlargement and may be able to lead an active life for many years.

Aortic incompetence is common and may be due to dilatation of the aorta or to changes in the aortic valves and may cause some of the symptoms. Congenital cerebral aneurysms are often present and may lead to fatal subarachnoid hæmorrhage, and though the risk of this is minimised by reduction of the blood pressure it is not entirely removed.

The condition can now be cured by operation but it is difficult to decide when it is indicated, as the prognosis is often good. Operation should be performed only by those with special experience, and even in such hands, the mortality is about 10 per cent, though this may continue to drop. If the patient has serious symptoms in childhood or if the blood pressure continues to rise much after 15 years of age, operation should be advised. After 20, the risks are greater and the anastomosis may be difficult or impossible, so that a greater degree of disability is needed to justify the risk.

(2) **ACYANOTIC WITH A POTENTIAL COMMUNICATION BETWEEN THE TWO SIDES OF THE HEART (Cyanose tardive)**

Pulmonary valvular stenosis is often found with a closed ventricular septum as well as with Fallot's tetralogy (see p 897). The stenosis may not be severe in spite of striking physical signs—a rough systolic murmur and thrill, maximal in the pulmonary area and sometimes a diminished and single second sound at this site—and

the patient may get on well for years. If the stenosis is more severe the right ventricle will hypertrophy greatly in the attempt to overcome the stenosis and the course will depend on whether the foramen ovale is sealed or not at the time when the pressure in the right atrium rises above that in the left. If it is sealed, a right-to-left shunt cannot develop and the patient will remain acyanotic. If it is not, the rising pressure on the right side will start a right-to-left shunt and a patient who has been acyanotic for years may become cyanotic (cyanose tardive). In both groups there will be increasing signs of right ventricular strain in the electrocardiogram and this is probably the best indication for operation, as it sometimes precedes symptoms that would call for operation and generally precedes much increase in the size of the heart.

The condition can be greatly helped by Brock's operation of valvotomy; and apart from the improvement in symptoms, the right ventricular strain may be relieved and the heart may become smaller.

(3) ACYANOTIC CASES WITH A LEFT-TO-RIGHT (arterio-venous) SHUNT.

Atrial septal defect.—This is very common but may not be recognised early as over half the patients first develop symptoms between 20 and 40 years of age. The volume of the shunt may be large, and one-third of the blood that reaches the left atrium may pass to the right, so that the pulmonary flow may be twice as large as the systemic flow.

Generally there is a systolic murmur in the pulmonary area and often at the apex also, and nearly a quarter of the cases have a diastolic murmur. The pulmonary second sound is widely split and may be loud. The heart is large with less disability than would be expected from this and the apex beat is tapping rather than heaving. The most distinctive feature is the pleonæmic lung with large pulmonary arteries and striking pulsation, often giving a hilar dance. The electrocardiogram generally shows partial bundle branch block (seen best in lead V₁) and often a long P-R interval with a large bifid P-wave.

Gradually the patient will become more dyspnoic and auricular fibrillation, which is rare in other congenital lesions, may be added. Thickening and fibrosis of the mitral valve, sometimes with mitral stenosis (Lutembacher's syndrome), is not uncommon. Towards the end as heart failure is developing, there may be slight cyanosis but not much more than with mitral stenosis. Hæmoptysis and, less commonly, pulmonary infarction may occur.

Ventricular septal defect.—A rough systolic murmur and thrill in the fourth left intercostal space are the signs that suggest this diagnosis. If there is little or no disability and a heart of normal size the defect is probably small, and this condition has been called the *Maladie de Roger*, though it is not as common as has been thought. The prognosis is excellent.

Larger defects are also common and produce a picture rather similar to atrial septal defect. The outlook is, however, more serious, partly because the pressure in the right ventricle and pulmonary trunk is more likely to rise high enough to reverse the shunt so that the patient becomes cyanotic (see Eisenmenger's complex).

Patent ductus arteriosus.—A continuous murmur through systole and diastole, generally best heard on the left side in the first and second intercostal spaces and high up under the left clavicle, is almost pathognomonic provided there is no cyanosis. Equally the thrill may be continuous or may be mainly in systole. If the ductus is large there is generally a wide pulse pressure and other signs similar to those of aortic incompetence, the extent of these signs, the size of the heart and the degree of dilatation of the pulmonary artery on radioscopy will give some measure of the amount of blood passing through the ductus. Generally the continuous murmur does not develop till the child is between 2 and 5 years old, and before this, with a systolic murmur only, no diagnosis can be reached without full investigations, which are not indicated at this age.

Occasionally the ductus may close spontaneously. In general the prognosis is

good until 30 or 40 years of age, but probably not for much longer. Bacterial endocarditis is a considerable risk, but is a less decisive indication for immediate operation now that it can be cured with penicillin. The condition is not often seen in patients over 40 years of age, probably because the ductus has closed or because a rising pulmonary pressure has arrested the flow during diastole and so changed the continuous murmur to one in systole only; there is some uncertainty about the relative frequency of these two developments. When pulmonary hypertension has developed the patient is likely to be much more disabled, and congestive cardiac failure becomes a serious risk.

This condition can be cured completely by operation which should be carried out as soon as there are significant symptoms or much enlargement of the heart. After 20, the advantages of operation should not be foregone in suitable cases, but the risk is greater and the disability may not justify it. It is essential to make sure that the patent ductus is the only lesion, for the slightest degree of cyanosis suggests some complication, and the patient might then be made worse by closing the ductus. Right ventricular preponderance in the electrocardiogram may be due to some complication or to pulmonary hypertension, and the patient must then have full investigations before an operation is decided on.

In experienced hands the risk of operation is as low as 2 or 3 per cent. If bacterial endocarditis is present when the patient is first seen, treatment with penicillin should be started at once and operation carried out when the patient is better. If the response is not good, operation should not be deferred, as it was sometimes curative before the introduction of penicillin; but the operative risk is then greater. The routine operation should be ligation of the ductus: the risk of recanalisation is slight.

(4) CYANOTIC CASES WITH A RIGHT-TO-LEFT SHUNT (*Morbus Cæruleus*).—The most striking feature of cyanotic heart disease is the appearance of the patient; this is due to the central cyanosis, the features of which have been described. It means that there is a right-to-left shunt and the picture is much the same whatever the anatomical abnormalities. In an attempt to overcome this lack of oxygen, the number of red cells and the hæmoglobin are increased; the latter is often 140 or even up to 180 per cent., and the former 7 or even 10 million per c.mm. The volume of the packed red cells (hæmatocrit) is also increased, often to 70 to 80 per cent. This is followed by the well-known picture of clubbing of the fingers and toes. Though the extra hæmoglobin is a great asset to the patient in overcoming his disability, the resulting increase in the viscosity of the blood may predispose him to thrombosis.

The disability may be severe and the patient may be able to walk a few yards only or up to a mile or so slowly. As a rule there is some correlation between the degree of cyanosis and of disability, but it is not always close, as the cyanosis depends on the size of the shunt and the percentage of hæmoglobin, and the disability more on the degree of pulmonary stenosis, when this is present.

The outlook is generally poor. Only one patient in two reaches the age of 7; one in five reaches the age of 14 and less than one in ten reaches the age of 21. The mortality during the first 3 or 4 years is very great, and continues at a lower rate up to the age of 18 or 21, when the small number surviving are the relatively mild cases with a fair expectation of life. Apart from the direct cardiac risks and the general frailty of these children, they have a special risk of bacterial endocarditis and also of cerebral abscess because organisms from the blood stream can pass direct to the brain instead of through the filter of the lungs.

(4A) CYANOTIC CASES WITH PULMONARY OLIGÆMIA.

Fallot's tetralogy.—The combination of pulmonary stenosis, a high ventricular septal defect, an overriding aorta, and right ventricular hypertrophy is known as Fallot's tetralogy, though all these features were emphasised by Peacock (1858). It is the most common form of morbus cæruleus (66 per cent.). The stenosis is at the infundibulum of the right ventricle in half the cases, at the pulmonary valve in a third and at both sites in the remainder.

This diagnosis can be made when cyanosis has been present from birth or from the first 18 months of life; when there is a systolic murmur of moderate intensity, often with a thrill, in the pulmonary area and a diminished or normal pulmonary second sound; when there is no diastolic murmur; when the heart is not much enlarged; when there is no prominence of the pulmonary arc or pulmonary arteries (though less than half of them show a real sabot-shaped heart, the remainder having a relatively straight left border or even slight prominence of the pulmonary arc due to dilatation of the infundibulum beyond the stenosis); and, most important of all, when the density of the lungs on radiography is lighter than usual. It is curious that four-fifths of the patients with Fallot's tetralogy should have the habit of squatting, though it is seen also in other forms of cyanotic heart disease, even in Eisenmenger's complex where there is no pulmonary stenosis.

These criteria should enable the diagnosis of Fallot's tetralogy to be made with confidence, and it is here and in simple pulmonary stenosis that surgical treatment is most successful.

Pulmonary atresia.—Cases with pulmonary atresia as well as those with pulmonary stenosis have been included as Fallot's tetralogy but the former must now be differentiated because the small and thin-walled pulmonary artery that is generally present beyond the atresia makes subclavian-pulmonary anastomosis more difficult but not always impossible. This diagnosis must be considered when there is the general picture of Fallot's tetralogy but no systolic murmur and a rather loud second sound in the pulmonary area, the aorta being more over to the left than usual. There may also be a continuous murmur, because the circulation to the lungs is helped either by a patent ductus arteriosus or by a bronchial artery that is large enough to produce such a murmur.

The only operative treatment is subclavian-pulmonary anastomosis, because the atresia generally involves too broad a section of the pulmonary valve region for a direct operation to be practicable.

Tricuspid atresia.—When there is the general picture of Fallot's tetralogy but a rather larger heart with hypertrophy of the left ventricle, and left ventricular preponderance in the electrocardiogram, the diagnosis is generally tricuspid atresia with a small or non-functioning right ventricle; there must be a defect of the atrial septum so that blood from the right atrium can re-enter the circulation. The aorta and pulmonary trunk may both arise from the left ventricle, in which case the lungs will not be oligæmic and the patient cannot be helped by operation. More often there is pulmonary stenosis, or the pulmonary trunk arises from a diminutive right ventricle reached through a ventricular septal defect.

This last group can be helped by subclavian-pulmonary anastomosis because they are suffering from a reduced pulmonary blood flow; but the improvement to be expected is less than and may not last as long as in Fallot's tetralogy. In both groups the prognosis is worse than in Fallot's tetralogy.

Pulmonary valvular stenosis with a right-to-left inter-atrial shunt.—This is the most common condition after Fallot's tetralogy in the oligæmic group. The physical signs are the same as in the acyanotic cases (see p. 895), but as the condition worsens the murmur and thrill may become much less evident. The electrocardiogram often shows the pattern of right ventricular strain, with deep inversion of T in leads II and III, and in the chest leads from V1 to V4.

The diagnosis should be suspected when cyanosis has developed later, sometimes not until early adult life. When this happens the patient generally becomes progressively worse, sometimes rather quickly, and operation should be considered at once. This must be pulmonary valvotomy, as subclavian-pulmonary anastomosis is liable to be followed by congestive heart failure.

SURGICAL TREATMENT OF CYANOTIC CASES WITH PULMONARY OLIGÆMIA.—The outlook of many of these children has been completely changed by the introduction

of subclavian-pulmonary anastomosis (Blalock-Taussig operation), and by Brock's operation for direct relief of the stenosis: here the stenosed valve is divided (valvotomy), or infundibular resection is performed, or both procedures may be needed. All these operations increase the blood flow to the lungs, and this brings more oxygen to the circulation and so the disability and cyanosis are both greatly relieved.

Whenever the disability calls for it, operation should be advised. Any indication that such a child is losing ground and is unable to walk as far as before is a sign of serious significance, and if anything is to be done it must be done quickly, as such deterioration is generally progressive until the child dies. This, unfortunately, applies only to children over the age of 3. However bad the outlook in young children, and this is often because of frequent attacks of increased cyanosis with unconsciousness, operation should be deferred, as in infants it is more dangerous and the improvement is often less lasting, because the anastomosis is too small as the child grows larger. For this reason operation should rarely be performed until the age of 3, or, if possible, 5 years of age. From then until 10 is perhaps the ideal age, though the results seem nearly as good in older children, and it is only in those over 20 that the risks seem much greater and the degree of improvement less.

The operation is a serious one with a mortality of about 5 per cent. in Fallot's tetralogy and much more in pulmonary atresia and the more complex conditions. The results are excellent in about three-quarters of these patients so that they may be able to walk a mile or more instead of 100 yards or so, and get about all day almost normally. The polycythæmia quickly diminishes or disappears and the clubbing of the fingers improves more slowly. The arm to which the subclavian has been divided gives no trouble.

It is important for the parents to realise that the heart condition has not been cured and that although the outlook is much improved it is still uncertain for how long this will last. The diminished blood flow to the lungs has been relieved by operation but the ventricular septal defect remains and the right ventricle is still working against the systemic pressure, whether the operation is an anastomosis or a direct one. One cannot, therefore, expect that the patient will be able to lead a more active life without some increase in the work of the heart. The heart increases in size in the first few months but generally not greatly, and so far, follow-up studies show that for 4 or 5 years the increase is not generally progressive or serious. Until however the ventricular septal defect can also be closed, the patient still has a limited outlook, and cardiac enlargement and increasing right ventricular strain will follow some day, but fortunately in most cases, not for several years.

(4b) CYANOTIC CASES WHERE THE PULMONARY BLOOD FLOW IS NORMAL OR INCREASED.—The diagnosis is best made by radioscopy, but physical examination may help, as large hearts and pulmonary diastolic murmurs are much more common in this group. If the pulmonary second sound is much increased and booming, or widely split, or if it is palpable, the patient probably has a raised pulmonary arterial pressure and an adequate blood supply to the lungs, so cannot be helped by operation.

In this group, accurate diagnosis is at present less important. Transposition and Eisenmenger's complex are the commonest lesions, the latter being the more likely diagnosis in adults.

Transposition of the aorta and pulmonary trunk.—In small children this is one of the commonest forms of morbus cæruleus but the mortality is heavy in the first years of life and relatively few survive. When both main vessels are completely transposed life would, of course, be impossible without some communication between the two sides. This may be through an atrial septal defect and a patent ductus arteriosus, when the outlook is very bad; or through a large ventricular septal defect when many patients who survive the first 2 or 3 years of life continue to carry on surprisingly well. The circulation is sometimes made easier by one of the main arteries being only partly transposed, i.e. overriding a ventricular septal defect.

Several forms of surgical treatment have been tried but at present the results are not good enough to justify the procedure

Eisenmenger's complex—This consists of the combination of ventricular septal defect, right ventricular hypertrophy, and overriding aorta. Patients with this condition have generally started as simple ventricular septal defects (see p 896) for the relative pressure in the two ventricles will decide whether there is a right to left shunt and cyanosis much more than the degree to which the aorta is overriding as nearly all ventricular septal defects are high up in the septum just below the aortic valve. Sometimes the pressure on the right side has been high from infancy and they have always been cyanotic and then they may be difficult to distinguish from cases of Fallot's tetralogy.

More often they become cyanotic later in life, perhaps when about 20. When this cyanotic stage is reached the pulmonary second sound is generally much increased, the pulsation of the pulmonary artery is easily palpable and as pulmonary hypertension develops the pulmonary blood flow diminishes. The patient becomes seriously limited but may be able to carry on quietly for some years. Restriction of activity and symptomatic treatment are the only useful measure that can be taken.

MAURICE CAMPBELL

THE HEART IN MISCELLANEOUS CONDITIONS

HYPERTHYROIDISM

Elevated basal metabolism is responsible for functional changes in the circulation in hyperthyroidism, but the high incidence of auricular fibrillation in thyrotoxicosis suggests that the heart may be directly affected by toxæmia. Increased tissue demands for oxygen are met by an increased cardiac output, which is characteristic of thyrotoxicosis. Circulating blood volume is increased and peripheral vasodilatation amounting to extensive arterio-venous shunting leads to an increased venous return. The increased cardiac output is achieved largely by an increase in heart rate, although there is some evidence that stroke volume is also elevated. The circulation becomes hyperdynamic and there is a greatly diminished circulation time. Tachycardia, hypervæmia and increased circulation velocity are well tolerated by the heart in young subjects with thyrotoxicosis although the metabolism of the myocardium is presumably pathological. The manifestations of thyrotoxic heart disease are auricular fibrillation and cardiac failure—these occur almost exclusively in the older age groups suggesting that degenerative changes in the heart are the cause of breakdown in the circulatory compensations for hyperthyroidism. The clinical features of congestive cardiac failure develop in spite of the high cardiac output. This apparent paradox is characteristic of thyrotoxic heart failure. Although the cardiac output is often higher than normal it is inadequate for the demands of the thyrotoxic state.

Symptoms—Palpitation, weakness and dyspnoea are common symptoms in thyrotoxicosis but these do not indicate heart disease. Palpitation may be continuous and regular and without apparent cause or it may be paroxysmal or continuous and irregular when due to multiple ectopic beats or auricular fibrillation. Palpitation may occur in young patients but it is more common in older patients with toxic adenoma. Dyspnoea and weakness are present in uncomplicated thyrotoxicosis but true cardiac dyspnoea develops only with the onset of cardiac failure, which is confined to the older age groups. Ischæmic cardiac pain may also occur in patients after middle life, and is probably due to latent coronary disease which is revealed by the increased cardiac work.

In thyrotoxic heart disease the general signs and symptoms of thyrotoxicosis may be obvious or they may be slight and easily overlooked. In particular the thyroid gland may not be visibly enlarged and only careful examination may reveal a small adenoma, or radiography may show an intrathoracic gland.

The signs of a hyperdynamic circulation are present; there is tachycardia, an increased pulse pressure with a moderately elevated systolic pressure and palpable digital arteries. The apex beat is increased in force and rate and the whole præcordium may pulsate with the heart beat. The first heart sound is loud, and it is usually followed by a systolic murmur which is best heard over the pulmonary artery and is in mid-systole. The second heart sound is not remarkable, and there are no murmurs in diastole unless there is associated valvular disease.

Auricular fibrillation is common in patients over the age of 45. It may be paroxysmal or permanent and is characteristically associated with chaotic high ventricular rates in untreated patients. Paroxysmal tachycardia and auricular flutter occur occasionally in hyperthyroidism. Congestive cardiac failure occurs when there is auricular fibrillation and severe thyrotoxicosis in the older age groups; it is shown by jugular venous congestion, pulmonary congestion and œdema, but there is often the distinctive paradox that the circulation remains hyperdynamic in spite of cardiac failure. Other forms of organic heart disease, especially hypertension, coronary disease or chronic valvular disease, are sometimes associated with thyrotoxicosis.

Radiology.—Cardiac enlargement is not present unless there is cardiac failure or associated heart disease. Thyrotoxic heart failure causes moderate generalised cardiac enlargement. An intrathoracic extension of the thyroid gland may be shown.

The *electrocardiogram* is not characteristic. Arrhythmia is confirmed when present. Changes associated with ventricular hypertrophy or ischæmia, such as T wave flattening or S-T depression, are present if there is additional organic heart disease.

Diagnosis.—Thyrotoxic heart disease is recognised in the presence of obvious hyperthyroidism by auricular fibrillation or the signs of congestive heart failure. However, many patients with thyrotoxic heart disease do not have obvious general signs of hyperthyroidism and the condition is therefore easily missed. Persistent tachycardia, unexplained auricular fibrillation, or unexplained heart failure, even in the presence of organic heart disease, indicate the possibility of hyperthyroidism, which may be further suggested by a history of weight loss, increased appetite, nervousness and other symptoms of Graves' disease. The diagnosis may be confirmed by radio-active iodine studies and tests of basal metabolism, which, however, are difficult to evaluate in the presence of heart failure. The differential diagnosis of the thyrotoxic state is considered elsewhere (see p. 494).

Prognosis.—The degree of damage to the heart in thyrotoxicosis depends on the age of the subject and the duration of the malady rather than on the type of goitre or the severity of the symptoms of hyperthyroidism. It is more serious with advancing age. The prognosis depends greatly on the successful treatment of the hyperthyroidism; congestive cardiac failure responds well and auricular fibrillation may cease spontaneously after treatment. The prognosis is poor if the hyperthyroidism is unrecognised and untreated, for the usual remedies of cardiac failure and auricular fibrillation are largely ineffective.

Treatment.—The primary object of treatment is the correction of hyperthyroidism (see p. 494). Although partial thyroidectomy is highly successful, the mortality is greater in patients with thyrotoxic heart disease than in those with uncomplicated Graves' disease. Surgical treatment will probably be replaced by medical methods in all patients with thyrotoxic heart disease. After correction of hyperthyroidism, congestive heart failure subsides and auricular fibrillation tends to be replaced by sinus rhythm. If the arrhythmia persists, quinidine should be used (see p. 828).

HYPOTHYROIDISM

The heart is affected in the majority of cases of advanced myxoedema. Basal metabolism is reduced and there is a corresponding reduction in cardiac output and peripheral blood flow. The circulating blood volume is low and venous return is diminished. At necropsy the heart is dilated and there is usually a large pericardial effusion. Coronary atheroma is common. Histological examination shows non-specific degenerative changes in the muscle fibres, and patchy fibrosis which is indistinguishable from that due to ischaemia.

Clinical Features—Angina pectoris occurs but other symptoms of heart disease are rare because physical activity is greatly reduced by the disease. Obvious congestive cardiac failure is unusual. The pulse is small and slow (50 to 60 a minute) and the venous pulse is not remarkable. The apex beat is not usually palpable and the heart sounds are soft. On radiography there is cardiac enlargement and diminished pulsation, the stencilled outline and globular shape of the heart is partly due to pericardial effusion, but in advanced cases there is also some dilatation of the heart. The pathogenesis of the effusion and cardiac dilatation is obscure.

The electrocardiogram shows bradycardia and low voltage of all complexes in all leads but the T waves are especially affected and may be isoelectric or inverted in leads showing left ventricular complexes, *see* in standard leads I and II and chest leads 4 to 7. These pathological changes become normal during treatment with thyroid. The electrocardiographic changes in myxoedema may be partially due to pericardial effusion. Diagnosis and treatment are described on pp 497-498.

ADDISON'S DISEASE

Cardiac disorder is not an outstanding feature of either diminished or increased function of the adrenal glands. In Addison's disease there are no cardiac symptoms but the heart is reduced in size and pulsation is diminished as shown by radiographic screening. The electrocardiogram shows varying changes which depend on the degree of electrolyte disturbance, the level of serum potassium appears to be the most important factor. All complexes tend to be of low voltage and the T waves may be isoelectric or inverted. Treatment with cortical hormones may at first cause further pathological changes in the electrocardiogram but if general recovery occurs the electrocardiogram tends to become normal.

DIABETES MELLITUS

Coronary atheroma and resulting ischaemic heart disease is frequently associated with diabetes mellitus. Acute coronary occlusion is common, in contrast to non-diabetic subjects with coronary disease it occurs frequently in young adults and in women almost as often as in men. Acute coronary occlusion with cardiac infarction frequently causes an increase in insulin requirements and may even precipitate diabetic coma. Prolonged good control of diabetes mellitus probably diminishes the risk of coronary atheroma but the relationship between treatment and the incidence of ischaemic heart disease is not very close. The electrocardiogram becomes abnormal in diabetic coma. T waves are especially affected and may be low or inverted the S T segment is depressed and the Q T interval is prolonged. As in other forms of endocrinopathy, the electrocardiogram can be related to electrolyte changes and recovery occurs after treatment.

HYPOGLYCAEMIA

Hypoglycaemia caused by therapeutic or spontaneous hyperinsulinism may produce acute coronary insufficiency in patients with coronary artery disease. The electro-

cardiogram may show profound ischaemic changes with S-T depression and T wave inversion in leads I, II and V5-V7. Recovery is usual but permanent muscle damage may occur.

BERIBERI HEART DISEASE

Wet beriberi is often associated with congestive cardiac failure. The condition occurs in Great Britain in mental patients, alcoholics and in other conditions associated with malnutrition. The symptoms are those of heart failure, the onset of which may be gradual or occasionally very acute. The heart is dilated; murmurs are not conspicuous but there is tachycardia and commonly a summation gallop rhythm. The clinical features of congestive heart failure appear, although the peripheral pulses and skin temperature suggest that the cardiac output is elevated above normal. The diagnosis should be considered in any patient with unexplained heart failure, especially if there is evidence of avitaminosis or nutritional disorder (see also p 469).

TRAUMATIC HEART DISEASE

The heart may be injured by direct penetrating wounds or by non-penetrating blows to the præcordium. *Penetrating wounds* are mostly caused by stabbing, gunshot or shell fragments, and rarely by fracture of adjacent sternum or ribs, the passage of a foreign body from the œsophagus, or paracentesis of the pericardium. Most deep, penetrating injuries are rapidly fatal, but recovery occurs in a considerable proportion when the injury is relatively superficial, especially when due to stabbing. Any part of the heart may be damaged. Penetration of the myocardium results in hæmopericardium and cardiac tamponade (see p 879). Wounds adjacent to the heart or grazing the pericardium tend to cause a serous pericarditis which is recurrent if a foreign body remains imbedded in adjacent tissues. The symptoms and sign are those of pericarditis, with or without an effusion (see p 878).

Treatment—The possibility of injury to the heart should be considered in all cases of penetrating chest injury. Hæmopericardium with tamponade requires urgent paracentesis followed by surgical evacuation of clot and repair of the wound as soon as possible. Deep, penetrating wounds may damage any structure of the heart and death is the usual result.

Non-penetrating injuries of the heart sometimes present difficult medico legal problems. A history of trauma to the chest followed by cardiac symptoms, which may be due to neurosis or natural heart disease, should be interpreted with the greatest caution. Blunt injuries to the anterior chest wall by heavy blows or crushing may injure the heart by causing sudden arrhythmia, contusion of the pericardium, myocardium or coronary arteries, and rarely by causing rupture of one of the valves, one of the cardiac chambers or the aorta. A previously diseased heart is more likely to be damaged by blunt trauma than a normal heart which, however, is not immune.

Arrhythmia—Palpitation and tachycardia is common after injury and is due to emotional disturbance, not infrequently associated with the possibilities of compensation. However, serious arrhythmia may be precipitated by blows of varying severity and by sudden immersion in cold water. Arrhythmia is probably induced by reflex action in most cases, but when the trauma is over the præcordium, contusion of the myocardium may be the cause. Transient auricular fibrillation is the commonest disturbance, sometimes it occurs in young subjects with a normal heart. Ventricular tachycardia and sudden death from ventricular fibrillation have been recorded after relatively trivial injury. Elderly subjects and those with coronary artery disease are probably the most vulnerable. Transient heart block may follow indirect trauma, the cause is presumably contusion of the conducting tissues but reflex inhibitions cannot be excluded.

Contusion Bruising of the pericardium and epicardium may result in transient pericarditis, pericardial effusion or hamopericardium. Spontaneous recovery is usual. Contusion of the myocardium causes varying degrees of muscle damage with or without damage to the coronary vessels, the right auricle, right ventricle, septum or left ventricle may be involved. The clinical features and electrocardiographic changes may be similar to those of cardiac infarction, cardiac pain of all degrees from a dull præcordial ache to severe widespread pain associated with fever and leucocytosis may result. Angina pectoris occasionally follows blunt injury which has involved the coronary vessels.

The electrocardiogram shows various changes in the ventricular complex, ranging from transient T wave flattening or inversion, and S T elevation or depression, to the development of pathological Q waves when there is extensive muscle necrosis. These changes are best seen in præcordial leads, but occasionally injury to the præcordium results in electrocardiographic changes indicating isolated damage to the septum or posterior wall of the ventricle.

Valve rupture may follow blunt injury or excessive effort in subjects with pre-existing heart disease. The aortic valve is most likely to be damaged in patients with syphilitic aortitis. The resulting acute aortic incompetence causes severe chest pain and left ventricular failure. Rupture of the mitral valve chordæ with resulting acute mitral incompetence has been recorded but it is also extremely rare.

TREATMENT OF DISORDERS FOLLOWING NON PENETRATING INJURY—Arrhythmia is usually of brief duration but if prolonged the appropriate anti arrhythmic drugs should be used (see p 828). Patients with cardiac contusion require bed rest for 3 to 6 weeks, depending on the severity of the damage. In rare cases where there is cardiac tamponade, paracentesis is indicated.

PSYCHONEUROSIS AND THE HEART

Synonyms—Cardiac Neurosis, Neurocirculatory Asthenia, Effort Syndrome, Da Costa's Syndrome.

The common symptoms of palpitation, flushing, sweating and hyperventilation associated with transient anxiety are well known to all. These physiological symptoms of alarm merge imperceptibly into the pathological when they become persistent and present without reasonable provocation. The somatic symptoms of increased cardiac activity induce further anxiety in susceptible individuals, the pressor reaction is reinforced and the mechanism becomes self-perpetuating. In some individuals alarm produces a depressor response in the vascular system as shown by a tendency to fainting, but there is much overlap between these interacting cardiovascular responses which are the manifestations of instability of the autonomic nervous system resulting from psychoneurosis.

The common psychological disturbance associated with cardiac symptoms is excessive anxiety with or without depression. In some patients the disorder is relatively superficial and is a transient reaction to external stress in a relatively sound personality, but in others the disorder is severe, endogenous and permanent. Functional cardiovascular symptoms occur in susceptible subjects when there is an excessive emotional reaction to real heart disease, when there is fear of sudden death or of a particular form of imagined heart disease, and it is in its most complete form in effort syndrome, which is essentially psychoneurosis with cardiac symptoms and signs of severe autonomic disturbance.

Clinical Features—Most patients have several symptoms, but any of the following symptoms and signs may occur alone, in combination or in any degree of relative severity.

Pain—Psychogenic "heart" pain is variable and contrasts at all points with true cardiac pain. It is rarely the central theme of a clinical history as in ischaemic

heart disease, and many patients wander off the subject into other troubles, or may be readily deviated into a discussion of other symptoms real or imaginary. Psychogenic pain is usually present for long periods; it may be made worse by effort but never brings the patient to a halt; it is usually in the left infra-mammary region and rarely radiates elsewhere, although some patients complain of discomfort in the left arm. It is described as stabbing, pricking, a dull ache or sometimes in bizarre terms which cannot be applied to pain at all, but it is never crushing or constricting as in angina pectoris. The mechanism of functional pain is obscure; often its severity and significance to the patient appears to diminish under interrogation. The important differential diagnosis is with angina pectoris, and musculo-skeletal lesions should be kept in mind.

Dyspnœa.—Breathlessness without effort or after slight effort is common. Respiration is often shallow, irregular and interrupted by deep sighs. It is never like the distressing dyspnœa of heart failure but a sense of suffocation is common. Occasionally functional hyperventilation may be prolonged to the point of tetany, but this symptom is unusual in effort syndrome, occurring mostly in monosymptomatic psychoneurotic females.

Palpitation from tachycardia and cardiac overaction is probably the commonest functional symptom of "cardiac neurosis". Palpitation is particularly responsible for the perpetuation of the vicious circle of anxiety and cardio-vascular symptoms. Exhaustion and weakness are also common complaints and transient giddiness, sweating and headaches are other common manifestations of vasomotor disturbance.

Signs.—The heart is usually normal but where functional symptoms are associated with heart disease the apparent severity of symptoms is incompatible with the physical findings. The general appearance of dejection, anxiety and tension often suggests the underlying psychogenic nature of the symptoms. Peripheral vasomotor disturbances are common: sweating is usually confined to the axillæ and palms of the hands; desquamation and eczematization of the palmar skin is common. Tachycardia, a hyperdynamic apex beat and high normal systolic level of blood pressure are the main cardio-vascular signs.

Diagnosis.—The diagnosis is made on a detailed analysis of the symptoms; their psychogenic nature is usually obvious. The signs of anxiety, autonomic disturbance and the absence of heart disease are confirmatory. When functional disorder and organic heart disease coexist, the symptomatology and severity of the organic lesion are incompatible. Effort syndrome must be distinguished from organic heart disease, hyperthyroidism and chronic disease causing loss of weight, weakness and tachycardia, such as pulmonary tuberculosis and reticulosis.

Prognosis.—Prognosis is concerned with the persistence of symptoms and ability to perform useful work, and this depends on the severity of the underlying psychiatric disorder. When symptoms are an acute reaction to external stress and there is no past history of psychopathology the prognosis is relatively good after the precipitating factors have been removed. When symptoms are insidious, unrelated to immediate external stress, and when there is a long history of psychoneurotic traits the outlook is correspondingly poor.

Treatment.—The first step in treatment is to give an explanation of the psychogenic nature of the symptoms, reinforced by an assurance that there is no organic heart disease. When the disorder is acute and in a relatively sound personality symptoms are normally cured by explanation and removal of the source of immediate stress. Rest is not generally indicated but sound sleep should be secured by sedation. In patients with long-standing psychoneurotic ill health the treatment is psychological, and reassurance about the heart is of little help and often tends to result in the appearance of other symptoms.

DISEASES OF THE BLOOD VESSELS

Diseases of the blood vessels are closely related to diseases of the heart, and combined cardio-vascular disorders now form the largest group of fatal diseases. Arterial degeneration, mainly by its effects on the heart and brain, is the commonest underlying factor. With advancing years there is a steadily rising incidence of ischaemic heart disease and cerebral vascular disorders, of the same order as the incidence of cancer. Examination of the Registrar General's returns over the past 20 years does not indicate any increase in deaths due to arterial disease apart from the greater incidence in the later decades due to longer survival, largely resulting from more effective treatment of infectious disease.

The mechanisms involved in the production of arterial degeneration are obscure, but advancing age, diabetes and high blood pressure are the chief contributory causes. High blood pressure is the result of increase in arteriolar tone. This may be secondary to renal disease or more rarely to endocrine dysfunction; but in the great majority of cases of arterial hypertension no organic cause for the increase in arteriolar resistance can be demonstrated. High blood pressure, whatever its origin, is a major factor in determining the age of onset and severity of atheroma, and coronary atheroma is the commonest cause of heart disease. Hypertension therefore not only increases the work which the heart must perform to overcome the increased peripheral resistance, but also leads to steady deterioration in the blood supply to the myocardium owing to coronary artery degeneration. Since atheroma is a generalised disorder, peripheral vascular disease, by which is usually meant occlusive arterial disease of the limbs, will frequently be associated with ischaemic heart disease and with the effects of arterial degeneration in other organs.

Maintenance of circulatory function involves the peripheral vessels no less than the heart. For example, after severe haemorrhage or fluid loss, the blood pressure is maintained by peripheral vasoconstriction. Failure of this compensatory vasoconstriction leads to a fall in blood pressure and is a major factor in the production of shock.

CLASSIFICATION OF ARTERIAL DISEASE.—Pathological processes in the arteries can be classified as follows:

(1) *Congenital*.—This group of arterial diseases is relatively small. It includes a number of developmental defects such as congenital aneurysm of the cerebral arteries, coarctation of the aorta and vascular tumours such as cirroid aneurysm.

(2) *Traumatic*.—Injuries to the peripheral vessels by penetrating wounds, particularly in the lower limbs, may lead to arterial obliteration or to formation of an arterio-venous aneurysm.

(3) *Inflammation*.—The arteries are particularly resistant to specific bacterial infections. Syphilis is exceptional in producing inflammation of the media of the aorta (mesaortitis) with destruction of elastic tissue; it also involves the cerebral vessels, producing endarteritis and thrombosis. Tuberculosis is also a cause of endarteritis. Arteritis may result from obstruction by infected emboli in bacterial endocarditis and weakening of the wall leads to mycotic aneurysm. Non-specific arteritis is a feature of a large and diverse group of disorders which are classified as allergic or collagen diseases. Sensitisation to some bacterial or chemical antigen is probably the common aetiological factor, and histologically, necrotic changes in the capillaries, arterioles or arteries are associated with a degeneration of collagen which leads to widespread changes throughout the body. Rheumatic fever, rheumatoid arthritis, periarteritis nodosa, disseminated lupus erythematosus, scleroderma and dermatomyositis are all diseases of this type.

Necrotising arteriolitis and endarteritis are also the characteristic lesions of malignant hypertension. Although morphologically there is a close similarity with the vascular lesions of the collagen diseases, the mechanism of their production in hypertensive states is quite different, being most probably related to excessive intra-vascular pressure which leads to acute ischæmia of the vessel wall.

(4) *Degeneration*.—By far the commonest and most important arterial degeneration is atheroma. This is a primary degeneration of the intima. Arterial stress or "wear and tear" is the chief predisposing factor, so that the maximum incidence is seen in old age and chronic hypertension. Disordered cholesterol metabolism may also play a part, and patients with diabetes, myxœdema and hypercholesteræmia are particularly prone to develop atheroma. Medial degeneration is less common. It is a disorder of old age and is usually associated with atheroma.

(5) *Neoplasm*.—True neoplasms of the arteries are rare. Angiomata affect the capillaries and are commonly found in the skin. Larger tumours, so-called cavernous angiomata, occur in the liver. Capillary angioma (hæmangioblastoma) occurs in the cerebellum in association with similar lesions elsewhere.

(6) *Local disorders of vascular tone*.—Excessive vasoconstrictor response to cold or mechanical stimuli produce digital asphyxia (Raynaud's phenomenon). Arterial spasm may also complicate arteriosclerosis. Other disorders of peripheral tone are erythromelalgia and erythrocyanosis. Disturbances of vascular tone may occur as premonitory symptoms in the collagen disorders.

SYSTEMIC ARTERIAL HYPERTENSION

THE NORMAL BLOOD PRESSURE.—There is a wide range of blood pressure in healthy subjects varying usually from 100 to 140 mm. Hg. systolic and 60 to 90 diastolic. The average normal is about 125/75 and a figure of 140/90 in an otherwise healthy adult may be taken as the upper limit of normal. A slight increase tends to occur with age. In the same individual, transient variations in blood pressure are common; nervousness, excitement, exertion, fatigue, cold and smoking may raise the normal level 20 or 30 points or more, but in these conditions the systolic pressure is affected more than the diastolic.

The systolic blood pressure is chiefly determined by the force of contraction of the left ventricle. The diastolic pressure is regulated by the arteriolar resistance, which converts the intermittent output of the heart into a continuous capillary blood flow. During systole the large musculo-elastic arteries are distended and during diastole their elastic recoil helps to maintain the arterial pressure.

Ⓐ **SYSTOLIC HYPERTENSION.**—A raised systolic pressure may be associated with a low, normal or high diastolic pressure. Increased emptying of the arterial system during diastole, either centrally as in aortic incompetence or peripherally due to vasodilatation as in thyrotoxicosis or severe anæmia, tends to lower the diastolic pressure and this is compensated by increase in systolic pressure. In such conditions, therefore, the pulse pressure is greatly increased. If the diastolic pressure falls considerably the pulse has a large volume and may be "water hammer" in type. A high systolic pressure with a normal diastolic pressure is seen in elderly patients in whom arteriosclerosis has impaired the elastic properties of the large arteries. Maintenance of the diastolic pressure then requires the production of a higher systolic pressure by the heart.

Ⓑ **DIASTOLIC HYPERTENSION.**—Apart from the various disorders enumerated above, systolic hypertension is always associated with elevation of the diastolic pressure, the primary dysfunction being increased arteriolar resistance. The common forms are essential hypertension and renal hypertension; less frequently diastolic hypertension results from endocrine disease.

(1) *Essential hypertension*—This is by far the commonest type of high blood pressure. The term *essential hypertension* is used to indicate the absence of any discoverable extravascular cause such as renal or endocrine disease. In benign essential hypertension (Hyperpiesia of Allbutt) clinical evidence of renal involvement is nearly always lacking. In malignant essential hypertension secondary arterial damage leads to rapidly progressive renal destruction, hypertensive encephalopathy and retinopathy develop as a result of vascular disturbance in the brain and retina.

(2) *Renal Hypertension*—The great majority of patients with renal disease develop high blood pressure. The usual cause is acute or chronic glomerulo-nephritis. Hypertension may be encountered in chronic pyelonephritis, congenital cystic kidney, tumours of the kidney, hydronephrosis and amyloid disease. Unilateral renal disease may also produce high blood pressure, the underlying lesion usually being pyelonephritis with congenital deformity of the kidney or more rarely tuberculosis, hydronephrosis, obstruction to a main renal artery or renal tumour.

(3) *Endocrine hypertension*—High blood pressure is a feature of adrenal cortical hyperfunction (Cushing's syndrome). This syndrome may be due to a tumour or simple hyperplasia of the adrenal cortex, or to cortical hyperfunction, without discoverable organic lesion. In severe progressive cases malignant hypertension may develop. Administration of cortisone or corticotrophin sometimes causes a sharp rise in blood pressure. Pheochromocytoma of the adrenal medulla or of ectopic medullary tissue may lead to attacks of paroxysmal hypertension. Eventually in this condition the hypertension becomes fixed at a high level and may pass into the malignant phase. The blood pressure may be raised in hyperthyroidism, usually the systolic pressure alone is raised but there may be an associated benign essential hypertension. High blood pressure is a frequent complication of diabetes and in this disease renal arterial and glomerular sclerosis may be an important contributory factor.

(4) *Other causes of diastolic hypertension*—In coarctation of the aorta the blood pressure may be considerably raised in the arms. In the lower limbs the systolic pressure is low but there is commonly slight diastolic hypertension which is probably due to renal ischaemia.

Organic disease of the brain may give rise to acute elevation of blood pressure. This is particularly encountered with rapidly expanding lesions, e.g. haemorrhage into cerebral tumours, and with sudden increase in intracranial pressure such as occurs after subarachnoid haemorrhage. Hypertension in renal disease is discussed on p. 1111. Further reference to endocrine disorders which produce hypertension will be found on pp. 516-518.

ESSENTIAL HYPERTENSION

The nomenclature of this condition is somewhat confused owing to the common use of the term *essential hypertension* in different senses. Thus it is sometimes applied to benign hypertension or it may be used to cover all forms of non renal hypertension. This confusion will be avoided if the term *essential hypertension* is restricted to those patients in whom no primary cause for the hypertension can be discovered. Such a definition would exclude primary renal and endocrine causes of all kinds. It would, however, include the malignant as well as the benign phase of the disease.

Ætiology—The cause of *essential hypertension* is unknown. There is no evidence that it is referable to organic disease of the renal arteries or arterioles. There are, however, certain facts concerning the development and incidence of *essential hypertension* which are important. There is a clearly recognised hereditary factor or more probably a combination of factors. The incidence is highest in the sixth decade and the disease is slightly more common in women, but more severe in its

course and complications in men. There is some racial variation, hypertension being rare in Chinese and in negroes in their native countries, although under western civilisation hypertension may be more common and more severe in negroes than in whites. In the benign phase hypertension is often labile and large variations may be produced by nervousness, emotion or activity. Later in the disease the level of blood pressure tends to become fixed even at rest, fluctuations diminishing in size and finally disappearing. There is evidence to suggest that transient hypertension occurring in times of stress may later become persistent; nevertheless, no consistent psychogenic factor can be demonstrated in patients with high blood pressure particularly when this is of the more severe type. The fact that sympathectomy may bring the blood pressure back to normal is not evidence of a neurogenic origin. Similar lowering of the blood pressure is often observed after non-specific operations and the blood pressure frequently returns to a high level after sympathectomy. Obesity is undoubtedly an aggravating factor in essential hypertension and the blood pressure is usually observed to fall with weight reduction.

BENIGN HYPERTENSION

Synonyms.—Hyperpiesia; Benign Nephrosclerosis.

Pathology.—The only morbid anatomical changes found in essential hypertension are secondary to the high blood pressure. They are of two main types; cardio-vascular hypertrophy, which is a direct response to the increased strain imposed on the heart and blood vessels, and arterial degeneration. In benign hypertension the degenerative process takes the form of fatty hyaline change in the arterioles with homogeneous swelling of the wall, but without necrosis. This is characteristically seen in the afferent arterioles to the renal glomeruli. In larger arteries a combination of medial hypertrophy and intimal thickening is seen, the latter being characterised by proliferation of elastic and fibrous connective tissue. In medium and large arteries atheromatous degeneration occurs in the intima and the atheromatous plaques may ulcerate or calcify and may be the site of arterial thrombosis. Occlusion of the lumen may lead to infarction, or embolism may occur from an arterial thrombus and lead to obstruction of more peripheral vessels. The cerebral, coronary, mesenteric and the peripheral arteries of the limbs are the sites of election for atheromatous degeneration and its sequelae. Progressive narrowing of arteries may lead to slow ischemia of tissues such as the myocardium, brain and kidney; obliteration of small arteries may lead to repeated focal parenchymal lesions as in cerebral arteriosclerosis and arteriosclerotic retinopathy. The pathological changes in malignant hypertension are described later.

Symptoms.—Benign hypertension may be symptomless for many years, particularly if the patient is unaware of its existence. The various clinical syndromes of the disease are in fact related to the degenerative changes in the organs resulting from arterial degeneration. Before manifestations of organic vascular disease appear, however, it is not uncommon for symptoms such as headaches, giddiness, nervousness and palpitations to arise. These may, on the one hand, be due to awareness of the high blood pressure and a fear of its consequences, particularly where there is a family history of vascular catastrophes. Or again these symptoms may be part of a general anxiety state, particularly in women at the menopause, for hypertension is likely to be discovered when menopausal symptoms first lead the patient to seek medical advice. Apart from these circumstances there is no doubt that some patients with benign hypertension develop headaches which are often severe, intractable and apparently related to the high blood pressure. They are often present when the patient awakens in the morning and may last for the greater part of the day. They may be associated with morning nausea or even vomiting. Not infrequently they

are migrainous in type and in such patients there may be a long history of migraine. There is no evidence that these headaches are due to organic cerebral vascular disease. The condition is not severe enough to warrant the diagnosis at this stage of hypertensive encephalopathy which is so common in malignant hypertension. If the level of the blood pressure is reduced by administration of sympatholytic drugs or by sympathectomy, dramatic relief of these headaches is usually obtained.

The majority of patients with benign essential hypertension will have no premonitory symptoms before the onset of organic complications. Breathlessness on exertion or, in more severe cases, paroxysmal nocturnal dyspnoea, indicates the development of myocardial insufficiency. Blurring of vision or sudden blindness in one eye may be due to hæmorrhage or thrombosis in one of the main cerebral veins or arteries. Hemiplegia results from cerebral thrombosis or from hæmorrhage commonly into the internal capsule due to rupture of the lenticulo striate branch of the middle cerebral artery, or subarachnoid hæmorrhage may result from escape of blood into the ventricular system. Focal paralyses occasionally occur, giving rise to diplopia, facial palsy or aphasia. Repeated attacks of paresis in one or more limbs may occur as the disease advances, and in older patients, progressive cerebral arterio-sclerosis may lead to focal or generalised convulsions and steady deterioration of intellectual power, ending in progressive dementia. Hæmorrhagic manifestations outside the brain are not common, but occasionally isolated attacks of hæmoptysis, hæmatemesis or hæmaturia are attributable to benign hypertension.

There are few physical signs until the advent of complications. The appearance may be plethoric and obese, or thin and pale. The radial and brachial arteries are usually thickened due to medial hypertrophy, and may be tortuous. The heart is often enlarged on clinical examination, the apex beat being forcible, the first sound at the apex loud or duplicated and the second aortic sound accentuated. Yet many patients, particularly women, continue with a high level of blood pressure for decades without appreciable evidence, clinical or radiological, of cardio vascular hypertrophy.

The fundi—Hypertensive retinopathy is a general term which covers a variety of retinal changes encountered in different types of hypertension. The retinopathy of benign essential hypertension represents the basic picture found in all forms of chronic hypertension and on this may be superimposed more severe lesions, for example in malignant hypertension or diabetes. The most constant feature is tortuosity of the arteries and nicking of the veins at the arteriovenous crossings. Very rarely the arteries are narrowed and threadlike but more often there is an obvious irregularity in calibre. The so called "silver wire" appearance of the retinal arteries is very inconstant and has no real diagnostic value. The veins usually appear congested. Superficial flame shaped or small discrete deep hæmorrhages may be seen in any part of the fundus, but are most frequent in the macular region, there are often associated but scanty grey or creamy exudates. Massive hæmorrhages may result from retinal vein thrombosis or the retina may be pale due to thrombosis in the central artery. Resolution of these lesions leads to sclerosis of obstructed vessels and neighbouring parts of the retina, pigment usually remains at the site of old hæmorrhages. When hæmorrhages or exudates occur near the optic disk some swelling of the disk margin may be observed. This is usually distinguishable from the papilloedema of malignant hypertension, as it is almost invariably unilateral.

As Allbutt pointed out, clinical evidence of renal involvement is rare, but nocturnal polyuria occasionally develops in severe benign hypertension. The presence of albumin in the urine is again rare and is usually attributable to advanced renal arterio-sclerosis, renal congestion due to heart failure, renal infarction or coincident diabetes. In elderly patients with longstanding benign hypertension and severe arteriosclerosis a slight to moderate degree of renal impairment may lead to reduction in tubular concentrating power and moderate elevation of the blood urea.

Course and Prognosis—Benign essential hypertension is compatible with a

long life and freedom from symptoms; nevertheless in most patients complications occur which shorten the expectation of life. Whilst the height of the blood pressure, particularly the diastolic pressure, is an obvious pointer to the severity of the disease, there is no method of forecasting if or when complications will occur. At any time, either for no obvious reason or during periods of severe mental or physical strain or in pregnancy, the blood pressure may rise to serious levels; periodic exacerbations may lead to repeated or progressive vascular damage in the heart, brain, retina or kidneys. Coronary thrombosis or a cerebral vascular accident may considerably lower the level of blood pressure and may so alter the patient's habits of life that the menace of the hypertension is greatly diminished. The prognosis is then that of the residual vascular complication.

Treatment.—In any individual it is impossible to prognosticate the course of the disorder or to prescribe a mode of life which will prevent complications. The introduction of active treatment by sympathectomy and hypotensive drugs has therefore aggravated rather than simplified the problem of treatment. To submit a patient to the trauma and risks of bilateral sympathectomy, or to commit him to a life of hexamethonium administration with its attendant side effects, are heavy premiums to pay for a doubtful insurance against uncertain hazards. On the other hand, when the complications have arisen these forms of therapy are even more hazardous and may be of doubtful or temporary benefit. In deciding on treatment various aspects of prognosis discussed above must be borne in mind. Hypertension is likely to run a more severe course, with cardiac and cerebral complications, in men than in women. The malignant change is rare, probably affecting less than 1 per cent. of patients, but a progressively rising diastolic pressure, exceeding 130 mm., is a warning sign. An occupation or mode of life involving excessive physical or mental stress is likely to have an unfavourable effect on prognosis. It is also axiomatic that the possibility of any primary cause for the hypertension must be excluded before active treatment is started.

—In asymptomatic benign hypertension, i.e. when the high blood pressure is discovered accidentally on routine medical examination, the fact should not be disclosed to the patient if it can be avoided, or if this is not practicable he should be advised that the condition is benign. Obesity should be treated by dietary restriction. In the present status of therapy there is no justification in attempting to lower the blood pressure by drugs or operation in the absence of symptoms. An exception may be made in young subjects, especially men, with a high fixed level of blood pressure (e.g. diastolic exceeding 130). In such cases it may be felt that complications are likely to occur sooner rather than later and for this reason some reduction of the pressure with hypotensive drugs is justifiable. The level may be regarded as fixed when considerable residual hypertension persists after 7 days' complete rest in bed with adequate sedation.

The second grade of severity includes those patients with symptoms which are not referable to organic vascular disorders. This is a miscellaneous group and for the most part the symptoms will be anxiety, headaches, dizziness, palpitations, various aches and pains, spots before the eyes and even breathlessness. As already explained, many of these patients will be women at the menopause and appropriate hormone therapy will often relieve the symptoms; otherwise reassurance, weight reduction and a placebo are indicated. In a minority of this group severe headaches occur, especially on waking and may be associated with nausea. Such headaches will often respond to aspirin or codeine, but failing these, benefit is sometimes obtained from ergotamine tartrate 1 mg. at half-hourly intervals until the headache passes off, but not exceeding three or four doses. If in spite of this treatment headache is incapacitating, associated with a high relatively fixed pressure and unaccompanied by other anxiety symptoms, administration of hypotensive drugs may be considered justifiable.

The third therapeutic group consists of those patients with benign hypertension in whom early evidence of arterial damage is found. Such evidence may be the appearance of superficial retinal hæmorrhages, a transient paresis, a mild attack of encephalopathy or the onset of dyspnoea on exertion.—Only a minority of these patients progress to the fully developed stage of malignant hypertension with papillo-œdema and renal failure. Nevertheless various other arterial complications may occur, especially in men, and it is justifiable to give at least a limited course of hypotensive drug therapy. The aim should be to produce an appreciable lowering of blood pressure which is sustained throughout the day without excessive swings and with minimal side effects. This is probably best achieved by a combination of drugs. Therapeutic trials of these are at present being extensively carried out. The most effective combination to date is an alkaloid, *Rauwolfia serpentina* together with a hexamethonium derivative, the latter being administered orally in the first instance or intramuscularly where a rapid depressor action is required. The dose should be determined for each patient by hourly blood pressure readings over 6 to 8 hours after the administration. The effect of these drugs is potentiated by a low salt diet. It must be appreciated that hypotensive drug treatment is not without its risks. Sympatholytic drugs may produce severe hypotension which may lead to syncope and occasionally to fatal cerebral hæmorrhage or thrombosis. Where severe coronary disease is present an attack of myocardial insufficiency may be precipitated by a sudden fall in blood pressure. A serious form of pulmonary œdema which may progress to consolidation has been described after prolonged hexamethonium therapy. Paralysis of accommodation may produce considerable incapacity for some time after the administration, and dryness of the mouth may be unpleasant. The former is best relieved by spectacles worn during the period of maximum action of the drug. Constipation, dysphagia and difficulty in micturition, drowsiness or lethargy may also occur. Prostigmine may relieve some of these symptoms. Very occasionally vagal inhibition of the bowel may lead to fatal ileus. Inadequate response to the hypotensive drugs or intolerance due to severity of side effects may lead to consideration of sympathectomy. This should be carried out only in patients with incapacitating symptoms which are judged to be due to the severity of the hypertension. The results in some cases are excellent, the blood pressure falling to the normal level and remaining there for many years. In other individuals there is sooner or later a gradual rise in blood pressure to pre-operative levels, but not infrequently hypertensive symptoms do not recur, possibly because a more steady level of hypertension is maintained without the periodic exacerbations which are responsible for ischæmic episodes or minor vascular occlusions.

The fourth grade of severity is characterized by obvious complications which result from arterial degeneration. Such are cardiac infarction, hypertensive heart failure, cerebral vascular accidents and severe grades of retinal vascular damage leading to impairment of vision; the latter include extensive hæmorrhages or exudates in the macular region, or thrombosis of main branches of the retinal vessels, but without papilloœdema. In patients who have sustained myocardial infarction or major cerebro-vascular accidents, treatment with hypotensive drugs or by sympathectomy is best avoided in view of the risks of lowering the blood pressure in the presence of occlusive arterial disease, but hypertensive heart failure or retinopathy may be dramatically improved by hypotensive drugs.

MALIGNANT HYPERTENSION

Synonyms.—Malignant Essential Hypertension; Malignant Nephrosclerosis.

The term malignant hypertension was first used to describe a syndrome consisting of very high blood pressure, transient cerebral attacks (hypertensive encephalopathy)

and retinopathy with papilloedema, occurring in a variety of disorders such as acute and chronic nephritis eclampsia and essential hypertension. Subsequently a number of writers applied the term exclusively as a clinical synonym for the malignant nephrosclerosis of Volhard and Fahr. Clinical and pathological studies have demonstrated, however, that the renal changes of malignant nephrosclerosis are not the cause of the hypertension, but develop during the course of the disorder. Furthermore experimental observations in animals have provided convincing evidence that the renal changes of malignant hypertension are directly attributable to severe elevation of blood pressure. It is now recognised, therefore, that malignant hypertension (with its associated nephrosclerosis) is a syndrome which may occur in any patient with severe hypertensive disease whether essential, renal or endocrine in origin. The clinical features and the hypertensive renal lesions which result are very similar whatever the origin of the hypertension.

Incidence and Pathology—It is not known what determines the transformation from the benign to the malignant form of essential hypertension. It is a feature of severe hypertensive disease that sudden exacerbations periodically occur. During these phases of very high blood pressure focal vascular damage may be produced in the brain, retina, kidneys and other viscera. The mechanism of this vascular damage is not clear, but there is strong experimental evidence that sudden increase in intravascular pressure may cause intense focal vasoconstriction and that this may lead to both vascular necrosis and perivascular tissue damage. In essential hypertension successive episodes of this character, manifested by attacks of encephalopathy, retinal hæmorrhage, heart failure or hæmaturia may be followed after a variable interval of months or years by the establishment of malignant hypertension which in the absence of treatment, progresses steadily without remission. This change from the phasic to the fixed stage of the disease may be due to progressive renal vascular damage maintaining and even aggravating the initial hypertension.

Two clinical groups have long been recognised, in the larger group the patients present with malignant hypertension in the fourth or fifth decades without a previous history of longstanding benign hypertension. The smaller group comprises patients, usually in the sixties, in whom longstanding benign hypertension changes to the malignant type. The progress of the disease tends to be much slower in the older age group and the development of renal failure may take several years. Owing to the growing frequency of routine blood pressure determination in young subjects there is increasing evidence that even in the first group symptomless hypertension may be present for many years before the malignant termination. It is uncertain what proportion of patients with essential hypertension pass into the malignant phase. Estimates from hospital practice are almost certainly too high and it is probable that the figure is not more than 1 per cent, possibly much less.

Malignant hypertension differs from benign hypertension essentially in the intensity of secondary vascular changes. Arteriolar degeneration is more acute and characteristically takes the form of fibrinoid necrosis of arterioles with endarteritis in the larger vessels. These changes are most prominent in the kidney, the afferent arterioles of the glomeruli undergoing necrosis whilst the interlobular arteries show endarteritis. The resulting acute ischaemia produces focal necroses in the glomeruli and hæmorrhage into the capsular space. Organisation of these acute ischaemic changes leads to gross distortion of the glomerular tufts, capsular adhesions, occasional epithelial crescent formation and chronic fibrotic thickening and occlusion of the arterioles. In addition there may be chronic ischaemic lesions of the glomeruli due to longstanding benign hypertension and for the same reason the larger renal vessels may show intimal fibrosis and elastosis together with medial hypertrophy. Hyaline droplet degeneration of the tubular epithelium is almost invariably present in the acute phases. Recurrent episodes of acute hypertensive damage lead to progressive involvement of the kidney and the final stage is that described as malignant

nephrosclerosis Here the architecture of the kidney is grossly disorganised, areas of interstitial fibrosis and tubular atrophy alternating with zones of dilated tubules. This focal destruction is presumably related to the arterial origin of the lesions. The histological picture of malignant nephrosclerosis may present a mixture of acute and organised lesions of the renal parenchyma. Occasionally acute arteriolar necrosis may be absent and the histological appearances may represent stages of organisation of the acute lesions.

The most diagnostic feature which differentiates malignant hypertension from chronic Type 1 nephritis is the relatively small reduction in the number of glomeruli and the large proportion of normal looking glomeruli relative to the degree of interstitial and tubular damage. This is consistent with the natural history of the disorder. Acute fibrinoid necrosis of arterioles and endarteritis is common in other organs particularly in the adrenal glands, pancreas and small intestine, less frequently in the brain, retina, liver and testis. As in the kidney, vascular lesions may lead to destruction of parenchyma, particularly in the pancreas. The rest of the body may, of course show changes referable to severe benign hypertension and chronic vascular degeneration, such as cerebral hæmorrhage, cardiac infarction and pulmonary oedema.

Symptoms—Malignant hypertension usually presents acutely with severe disabling symptoms in a previously healthy middle aged adult. An analysis of a series of 100 cases showed headache as a presenting symptom in 76, dyspnoea in 54 with nocturnal attacks in 14, visual impairment in 51, frequency of micturition in 49, vomiting in 44, dependent oedema in 23, weight loss in 19, hæmaturia in 17, giddiness in 15 and organic paralysis in 11. Epistaxes, hæmoptysis, hæmatemesis, mental confusion, convulsions, abdominal pain and pain in the loin were occasional symptoms.

Headache, the commonest early manifestation, usually occurs on waking in the morning and is frequently associated with nausea or vomiting. It may last for a few hours or throughout the day and is generally localised in the frontal region or vertex. The attacks are sometimes limited to one day of the week, usually Sunday, when the patient breaks his normal early morning routine. Severe sub occipital headache should suggest the possibility of subarachnoid hæmorrhage. Paroxysmal nocturnal dyspnoea may be a prominent symptom before there is any complaint of dyspnoea on exertion, these attacks of pulmonary oedema are often accompanied by a distressing cough with frothy bloodstained sputum. Signs of right heart failure are almost always inconspicuous and if present at the onset should suggest an independent cardiac lesion. Polyuria, especially at night, may be sufficient to cause severe thirst and considerably increased fluid intake. Hæmaturia may be a solitary symptom and because of its painless, profuse character may suggest a surgical lesion of the urinary tract, intense necrotising lesions in the kidney are usually found in such cases. The characteristic visual disturbance is blurring of vision which is due, not to papilloedema, but to the presence of exudates or hæmorrhages, or both, in the region of the macula. Although transient paralysis or a mild convulsive attack may occasionally be an early symptom, fully developed hypertensive encephalopathy is not usually seen until later in the disease. The characteristic features of these attacks are disorientation, often with mental excitability and gross abnormalities of behaviour, there may be severe headaches, convulsions, complete blindness and coma. All these symptoms may be reversible and rapid improvement usually follows administration of hypotensive drugs. Organic cerebral vascular lesions may, however, occur in the course of an attack, leaving permanent paralysis. In occasional patients episodes of abdominal pain may be extremely severe and give rise to anxiety. There is no doubt that such symptoms can be produced by vascular necroses in the gut, and intestinal obstruction due to this cause has been described. Testicular and gall bladder pain may be due to acute vascular lesions in these organs.

On examination the clinical signs are unmistakable. In the early stages there is a striking contrast between the apparent physical well being of the patient and the

grave prognosis Hypertension is severe, with systolic pressure over 220 mm and diastolic over 120 mm in the majority of cases During the course of the disease there is little fluctuation in blood pressure even in response to prolonged rest or after the development of heart failure, in fact there may be a progressive rise Cardiac arrhythmia is rare There is marked cardio vascular hypertrophy with obvious thickening of the radial and brachial arteries and enlargement of the heart Papilloedema is the diagnostic sign of malignant hypertension It is bilateral and is usually associated with retinal oedema, hæmorrhages and exudates Retinal oedema or exudates may produce a "star figure" radiating from the macula Other retinal lesions occasionally seen are thrombosis of a large retinal artery or vein, subhyaloid hæmorrhages and retinal detachment Pulmonary oedema produces fine inspiratory crepitations at the lung bases and in paroxysmal dyspnoea these may be widespread and associated with rhonchi

In the early cases of malignant hypertension there may be no evidence of renal involvement In most cases, however, there is albuminuria, which varies from a trace to as much as a third volume on boiling Obvious or microscopic blood may be found, but urinary casts are not commonly present The specific gravity of the urine is usually fixed at 1.010 to 1.012 when the patient is first seen and renal function tests show diminished tubular concentrating power Nitrogen retention is, however, usually absent and in many cases the disease runs its whole course without the development of more than moderate elevation of the blood urea In the active stages the blood count frequently shows a polymorphonuclear leucocytosis and rapidly developing anaemia The plasma protein level is not appreciably diminished

Course and Prognosis—In the absence of treatment malignant hypertension is a progressive disorder and there may be rapid deterioration with a fatal outcome within a few months of the first symptom In most series of cases the average prognosis is given as 1 to 2 years, the expectation of life being rather longer in women than in men Very occasionally the disease appears to pass into an inactive phase which may continue for several years before a further deterioration sets in During this period there may be no evidence of new vascular lesions, papilloedema may subside and exudates resolve, the margins of the optic disk often remain indistinct with filling in of the optic cups but there is no true swelling This appearance is sometimes called secondary optic atrophy Albuminuria may diminish and even cerebral symptoms and breathlessness may improve Nevertheless in most cases the rapid deterioration, and the distressing nature of the later symptoms due to a combination of pulmonary oedema, renal failure, hypertensive encephalopathy and retinopathy, justify beyond any terminological scruple the name malignant hypertension

Diagnosis—The presence of papilloedema is the all important diagnostic sign which differentiates malignant from benign hypertension The separation from chronic nephritis and from other types of renal disease in which the hypertension has become malignant may in the late stages be extremely difficult In general, papilloedema does not develop in primary renal disease until the patient has reached an advanced stage of renal failure In chronic uræmia the urine is usually colourless due to absence of urochrome, whereas in malignant essential hypertension the urine is usually well coloured When renal function tests are unimpaired it is important to exclude unilateral renal disease Intravenous pyelography will usually show such an abnormality either in the form of a non functioning kidney or a grossly contracted kidney with deformity of the renal calyces If the intravenous pyelogram appears to be in any way abnormal, direct pyelography should be carried out on the affected side in order to obtain a more accurate picture The third problem is the differential diagnosis between malignant hypertension and intracranial tumour Both conditions may present with papilloedema and focal neurological signs Cerebral tumour may occur in a patient with benign hypertension or more rarely may itself cause hypertension If marked albuminuria is present, and particularly if there is renal

impairment, a diagnosis of malignant hypertension should be made. In the absence of renal involvement full investigation for a space occupying lesion should be carried out.

Treatment—In the later stages when renal function tests are impaired, treatment can be only symptomatic. If, however, the blood urea is within normal limits or only slightly elevated (e.g. to not more than 60 mg. per cent.) attempts should be made to lower the blood pressure by sympathectomy or hypotensive drugs. In older patients or in those with severe vascular complications, such as heart failure or cerebral hæmorrhage, sympatholytic drugs will be preferred. In younger patients a course of drug treatment should be given a trial, hexamethonium salts being given as described under treatment of severe benign hypertension. The result may be considered satisfactory if symptoms can be relieved, papilloedema subsides and the blood pressure is stabilised at a lower level than previously. It is usually impracticable and unnecessary to try and reduce the blood pressure to normal. If this degree of control cannot be achieved or if side effects of the drugs are incapacitating, bilateral thoraco dorsal sympathectomy offers the only chance of delaying the progress of the disease. In general this operation should be reserved for patients under the age of 50 with normal renal function and without evidence of coronary disease or severe cerebral vascular damage. In addition to these hypotensive measures, symptomatic treatment for headaches and breathlessness and other hypertensive manifestations should be carried out as described under benign hypertension.

PULMONARY HYPERTENSION

Systemic hypertension is not associated with a rise in pulmonary arterial pressure. Pulmonary hypertension is due to a variety of lesions all of which produce either increased peripheral resistance in the lungs or increased output of the right ventricle or both. Mitral stenosis, emphysema, pulmonary fibrosis due to any cause, primary pulmonary endarteritis and certain types of congenital heart disease are the common ætiological factors (see p. 895).

HYPOTENSION

There is no arbitrary limit which supplies a satisfactory definition of hypotension, but in adults 100 mm. may be regarded as the lower limit of the systolic pressure. The reading may be slightly lower in the supine than in the erect position.

Ætiology and Pathology.—Abnormally low blood pressure may be due to myocardial infarction or reduction in cardiac output due to terminal heart failure. Reduction in cardiac output may also be due to diminished venous return in oligæmic states, e.g. following hæmorrhage, loss of fluid due to burns or acute gastro-enteritis. Severe toxæmia may also produce an abnormally low blood pressure and so may heat exhaustion. In vasovagal syncope hypotension is a usual feature. Low blood pressure is a characteristic of Addison's disease. Postural hypotension is a specific variety which will be described separately.

Symptoms—In acute hypotension due to oligæmia the skin is cold and clammy, the pulse is usually rapid and small in volume, the blood pressure may be unrecordable or the sphygmomanometer may register the systolic but not the diastolic pressure. Hypotension with bradycardia, nausea and sweating suggests a vasovagal attack. In shock there will usually be evidence of a primary cause and the hypotension is chiefly important as an index of deterioration or recovery.

Prolonged hypotension is sometimes associated with states of unconsciousness following head injury or operations on the brain. In these and in other patients

with prolonged hypotension, renal function may be considerably impaired and elevation of the blood urea may be associated with hyperchloræmic acidosis.

Treatment.—This depends upon the cause. Hypotension following hæmorrhage is a grave sign and usually indicates a loss of at least 25 per cent. of the blood volume. Transfusion of whole blood should be given until the systolic pressure reaches 100 mm. After this point, a further 2 pints are usually necessary to restore the blood volume.

POSTURAL HYPOTENSION

Postural hypotension is present if the systolic pressure in the erect posture after 3 minutes' quiet standing, with the arm at heart level, is 50 mm. or more below the systolic pressure in the supine position.

Ætiology.—This disorder is due to impairment of the carotid sinus reflex. It may follow bilateral denervation of the carotid sinus or may be associated with neurological or endocrine disease, particularly tabes dorsalis, syringomyelia, diabetic neuritis, Parkinsonism, Addison's disease or hypoparathyroidism. It may follow extensive sympathectomy or the administration of drugs paralysing the vasoconstrictor nerves. In many cases, however, there is evidence of widespread disorder of the autonomic nervous system unaccounted for by any organic lesion. To this condition the term idiopathic postural hypotension has been given. The central lesion in such cases is above the spinal reflex level and is probably a specific autonomic degeneration resembling Parkinsonism. It is rare before the age of 40 and uncommon in women.

Symptoms.—The cardinal symptom is syncope, usually preceded by dizziness. It rarely occurs while the patient is sitting and never while lying down. Attacks are usually more frequent early in the day, during hot weather and on standing still after moderate activity. They are often first noticed while standing in queues or at the kitchen sink. In most cases, especially of the idiopathic type, the pulse rate is unchanged despite great variations in blood pressure. There may also be patchy or total anhidrosis, nocturnal polyuria and, in males, loss of libido and potency. Pigmentation of the skin is sometimes observed and hyperhidrosis has been reported. There may be absence of pupillary reaction to light.

Diagnosis.—Epilepsy is usually suspected until the postural variation in blood pressure is discovered. The presence of pigmentation may suggest Addison's disease, but again the demonstration of a gross fall in blood pressure on standing still, establishes the diagnosis.

Prognosis.—Postural hypotension may persist unchanged for very many years with minor disability or it may progress to a disabling affliction which confines the sufferer to a wheel-chair. Remissions rarely occur. The postural hypotension which follows dorso-lumbar sympathectomy usually passes off in 6 to 9 months. More extensive sympathectomy may be followed by a permanent, disabling, postural hypotension.

Treatment.—Elastic stockings and an abdominal binder are useful measures to diminish pooling of the blood. Symptoms may be improved by avoiding the supine position at all times during the day and elevating the head of the bed 18 inches at night. Treatment with vasoconstrictor drugs usually produces little if any permanent relief of symptoms, but is worthy of trial.

PERIPHERAL VASCULAR DISEASE

The term peripheral vascular disease includes a number of obliterative arterial diseases of the limbs and a group of less common functional disorders of the small peripheral vessels.

There are two main types of obliterative arterial disease :

(1) *Chronic vascular occlusion* due to arterial degeneration or vascular spasm, or both processes in combination. The commonest variety of peripheral vascular disease is atheromatous degeneration which may be complicated by vascular spasm and by thrombosis. Detachment of thrombus from an atheromatous area may give rise to embolism in a more peripheral artery. Raynaud's phenomenon is an example of vasospastic peripheral arterial disease, but this also may in the later stages be complicated by thrombosis.

(2) *Acute obstruction* to the vessel lumen by embolism. Systemic emboli usually arise from the valves of the left side of the heart or from mural thrombi in aortic or ventricle or from thrombosis over atheromatous areas of the larger arteries.

Peripheral vascular disease of all kinds leads to ischæmic manifestations in the limbs, the chief of these being muscle pain and gangrene.

METHODS OF INVESTIGATION.—Since peripheral vascular disease is most commonly due to generalised arterial degeneration a complete examination of the cardio-vascular system is essential in all cases. This involves examination of the peripheral arteries of the upper and lower limbs, retinoscopy, examination of the heart and the blood pressure. Electrocardiographic investigation and radiography of the heart and aorta should be carried out, and the urine should be tested for sugar and albumin. The Wassermann reaction must be tested in all patients with indolent ulceration of the limbs. Radiographic examination of the affected parts for arterial calcification is of value in distinguishing arterial degeneration from inflammation. In all cases of deep ulceration, radiography of the underlying bones and joints is essential for the detection of osteomyelitis or destructive arthritis.

Local examination of an affected limb should be directed first to the colour of the skin, which is determined by the filling of the sub-papillary venous plexus and by the proportion of reduced hæmoglobin in the blood. Pallor is usually due to arterial occlusion or vasoconstriction, cyanosis to slowing of the blood flow, redness to capillary dilatation, which may be persistent or may be transient if due to inflammation or reactive hyperæmia. Engorgement of the superficial veins should be looked for. Inspection will also reveal the presence of oedema which may be inflammatory or may indicate venous obstruction. Oedema is sometimes present in the chronic ischæmic limb, especially where there is under-nutrition of the tissues and muscular atrophy due to disuse. Trophic lesions should be observed in their general extent and for the presence of sinuses indicating involvement of deep tissues. Associated eczema or fungus infections between the toes should be noted. The skin temperature is regulated by rate of blood flow and the comparison should be made of normal and abnormal limbs. Lowering of skin temperature indicates arterial occlusion or vasoconstriction, while increase is usually due to inflammation. Pulsation should be looked for in all the main arteries of the limb, e.g. in the lower limb the femoral, popliteal, posterior tibial and dorsalis pedis arteries, the two sides being compared. If there is a marked difference in pulsation the blood pressure should be compared on the two sides.

Special investigations may be carried out to determine the extent and severity of the vascular occlusion. A simple test is to elevate the lower limb and then measure the time taken for the circulation to return to the toes after hanging the leg downwards. In the normal limb, provided it is warm, this should take a few seconds, but in vascular occlusion it may be increased to half a minute or longer. The amplitude of pulsation at different points in the main arteries may be measured by the recording oscillograph. In skilled hands this may indicate the site of vascular obstruction, which is of special value when the level of amputation is being considered. Measurement of skin temperature can be used to determine whether ischæmia can be relieved by sympathetic vasodilatation. In the reflex vasodilatation test the patient is placed in a hot chamber with the affected limbs outside. Alternatively, reflex vasodilatation

may be produced by putting the arms in hot water (when the skin temperature of the feet is to be tested) until general vasodilatation and sweating occurs. With the room temperature about 20° C. reflex vasodilatation should produce in the normal a rise in skin temperature over the hand or foot to at least 30° C. Sympathetic release may also be obtained by spinal anaesthesia and this method is preferable if sympathectomy is being considered as a form of treatment. In all these investigations, if only one limb is affected, the sound limb should be used as a control.

Angiography is a valuable method of investigation. If arterial grafting is contemplated it is essential both for diagnosis and for assessment of the results of treatment. Angiography will indicate not only the site and extent of vascular occlusion, but will give some information as to the degree of collateral circulation. Satisfactory arteriograms of the limb vessels can be obtained by injection into the femoral artery of 50 per cent. diodone.

PERIPHERAL ARTERIOSCLEROSIS

Ætiology and Pathology.—The all important pathological lesion in peripheral arteriosclerosis is atheroma. The commonest predisposing factors are old age, high blood pressure and diabetes; in other conditions characterised by a raised blood cholesterol, e.g. myxœdema, atheromatous degeneration may be particularly severe. Atheroma starts with the deposition of doubly refracting lipid in the deep layers of the intima; cellular infiltration and fibrosis follow, and a raised nodule is produced in the vessel wall. Cholesterol crystals are formed and calcification usually occurs. The lesion is common in areas of strain, particularly at points of bifurcation or of origin of branches of the aorta. Ulceration may occur in atheromatous areas and localised thrombosis may complete the arterial occlusion. Medial degeneration (Mönckeberg's degeneration) is a much rarer form, which leads to ring-like calcification of the media and this may be recognised radiologically. It occurs in elderly patients and atheroma is almost always present. Arterial degeneration is most common in the lower limbs and the popliteal artery is the site of election. Occasionally arteriosclerosis in the arteries of the upper limb produces ischæmic pain, numbness and blanching of the digits.

Symptoms.—Peripheral arteriosclerosis is five times as common in men as in women. The two cardinal manifestations are pain and ischæmic necrosis of the tissues. The usual type of pain is *intermittent claudication* (angina cruris). This consists of cramp-like pain in the calf, produced usually by a constant amount of exercise, and relieved promptly by rest. This distribution of pain is due to popliteal artery occlusion. Less frequently the obstruction is in the femoral or common iliac artery and claudication pain may then occur in the thigh or gluteal region. Claudication may first affect one side and later, as improvement occurs with the development of collateral circulation, the other limb may in turn be affected. As the disease progresses effort pain is characteristically brought on by diminishing amounts of exercise, until the patient may be unable to walk more than 10 or 20 yards. *Rest pain* is a continuous type of pain which affects the distal portions of the feet or toes. It usually comes on at night when the patient gets warm in bed, and relief may only be obtained by hanging the foot downwards out of bed. Rest pain is very often resistant to all forms of drug treatment and may be so incapacitating that amputation is necessary. The ischæmic lesion is in general very severe in these cases and gangrene is a common sequel. Rest pain may also be produced by inflammatory changes associated with gangrene, especially if there is considerable œdema or deep necrosis with involvement of bone or joints.

Gangrene due to arteriosclerotic occlusion is common in the lower limb but rare in the upper. It may involve one or more toes, or the distal part of the foot according

to the particular arterial branch which is obstructed. Trauma is a frequent precipitating factor, bruising of the foot leading to oedema and thereby depressing the local circulation to a point below which effective nutrition cannot be maintained. In other cases gangrene may appear or extend suddenly in a manner which indicates either embolism or acute extension of a thrombotic lesion. Gangrene may also occur over pressure points, especially the ball of the heel and the malleoli. Trophic ulceration may be observed in the absence of massive tissue necrosis. This may take the form of ulceration around the nails or between the toes and the condition may be aggravated by fungus infection or an eczematous eruption. All forms of infection tend to aggravate ischaemia by producing oedema, but the introduction of antibiotic therapy has made it possible to combat moist, spreading gangrene with satisfactory delimitation of the lesion. Vascular spasm is sometimes a prominent feature in peripheral arteriosclerosis and the appearances may resemble Raynaud's phenomenon due to other causes. Sometimes individual digits are affected (so-called "dead fingers") particularly after exposure to cold. The combination of arterial degeneration with secondary vasoconstriction may lead to symmetrical peripheral gangrene of the fingers or toes.

The physical signs which may be present in obliterative endarteritis have been discussed under methods of investigation. Pallor or cyanosis of the skin will depend on the degree of arterial occlusion. Skin temperature is lower on the abnormal side unless inflammation is present. The femoral pulses will usually be diminished in amplitude and the posterior tibial and dorsalis pedis pulses are frequently absent. It should be noted, however, that dorsalis pedis pulsation is absent in about 10 per cent of normal young adults. Popliteal pulsation is sometimes difficult to feel in normal subjects and this sign is equivocal unless there is a definite difference between the two sides.

Diagnosis.—The diagnosis of obliterative arteriosclerosis is indicated by the age of the patient, generalised signs of arterial degeneration and evidence of predisposing factors such as hypertension or diabetes. The radiological demonstration of calcification is a conclusive sign of arterial degeneration. Difficulty arises over the occasional young patient in whom localised atheroma produces obliteration of a large artery in one of the limbs. The differentiation from thrombo-angiitis in these cases is difficult; the absence of recurrent episodes and of associated venous thrombosis are the most important diagnostic points in favour of arteriosclerosis.

Course and Prognosis.—Peripheral arteriosclerosis produces a permanent and usually progressive obliteration of the arteries. After an initial attack of intermittent claudication or gangrene, considerable improvement may occur over a long period of time with establishment of collateral circulation. The treatment of infection with antibiotics, with subsidence of oedema, frequently leads to considerable healing and makes local surgery a practical measure. It is common for both lower limbs to be involved in sequence although, of course, intermittent claudication occurs only in the more affected limb. The individual prognosis is frequently determined by the consequences of arterial degeneration elsewhere in the body. Thus relief of angina pectoris is sometimes followed by the onset of angina pectoris as the patient returns to normal activity.

Treatment.—The most essential treatment in patients with peripheral arteriosclerosis is prophylaxis. The foot should be kept clean and warm and at all costs trauma should be avoided. Thus special shoes should be fitted if necessary and warm, woollen socks should be worn. Exposure to cold and wet should be carefully avoided. When vascular occlusion gives rise to definite ischaemic changes, complete rest in bed is necessary, extremes of heat or cold should not be permitted to the affected part and bed socks should be worn. The treatment depends on the nature of the disorder. Intermittent claudication may gradually improve with the passage of time as collateral circulation develops. This may be expedited by the use

of intermittent venous occlusion, but only if treatment is continued over a long period. Sympathectomy is of uncertain value, some cases being improved, many obtaining no relief. The skin temperature response to sympathetic release gives no reliable indication of the increase in muscle blood flow and relief of symptoms which may be expected after sympathectomy. In selected cases severe claudication may be successfully treated by section of the tendo achillis. Vasodilator drugs are of little value.

Rest pain is treated by putting the patient to bed and giving analgesic drugs. Intermittent venous occlusion may be tried; occasionally this kind of pain, particularly if of sudden onset, may gradually improve with the development of collateral circulation. In intractable cases, however, amputation may be necessary.

Gangrene is now treated conservatively in the majority of cases. Rest in bed and use of antibiotics quickly lead to the subsidence of inflammation and demarcation of the area of gangrene. Necrotic tissue may then be removed and healing accelerated by means of pinch grafting. Where gangrene is superficial and when considerable improvement in the skin circulation follows reflex vasodilatation, sympathectomy may be the most effective treatment particularly when secondary vasoconstriction is a prominent feature. In resistant cases, particularly in elderly subjects with generalised arteriosclerosis or diabetes, mid-thigh amputation may be the only effective form of treatment. Recent developments in the cold preservation of human tissues have made arterial grafting a practicable form of therapy in arterial disease. This is obviously most successful where a local lesion occurs in an otherwise healthy vessel, e.g. traumatic arterial occlusion or localised degeneration.

THROMBO-ANGIITIS OBLITERANS

Synonym.—Buerger's Disease.

Definition.—A disease characterised by acute inflammation with thrombosis affecting both arteries and veins.

Ætiology.—The disease has been recorded in all countries and races. The cause is unknown. It affects men almost exclusively and 99 per cent. of cases are smokers, most of them heavy smokers. Attempts to demonstrate an infective cause or an allergy to nicotine have been inconclusive. The association of non-specific inflammation of arteries and veins suggest a relationship to periarteritis nodosa and the other collagen diseases. Some patients develop visceral vascular lesions and the relationship to the collagen disorders is even more marked in these cases.

Pathology.—Any vessel may be affected, but the medium-sized arteries and veins of the lower limbs are most commonly involved. It is likely that the earliest change is a proliferation of the intima and infiltration with small round cells. When thrombosis has occurred there is a marked intimal proliferation with a few foci of lymphocytes. The other coats show the usual changes associated with thrombosis, fibroblastic response in the media and capillary dilatation with fibroplasia in the adventitia. As the lesion ages, fibrosis occurs in the thrombus and recanalisation follows. Characteristically only a short length of the vessel is affected and lesions in all stages, with intervening normal areas, may be found.

Symptoms.—These depend on the vessel involved. The most usual symptom is intermittent claudication, but patients may present with superficial venous thromboses, Raynaud's phenomenon, gangrene of the extremities or a visceral catastrophe. Venous thrombosis commonly affects the lower limb and characteristically produces episodic attacks of localised, superficial, painful swelling, particularly in the calf. Peripheral gangrene may affect the toes, or a larger part of the extremity if a main artery is obliterated. Pain in the feet at night is not uncommon, and is characteristically eased by hanging the leg downwards out of the bed, or by walking about.

Paræsthesiæ may occur. Ischæmic pain in the arms is rare but may be severe enough to prevent the patient from following his usual employment. Cardiac infarction or cerebral thrombosis may occur.

The physical signs depend on the site and age of the lesions. When a main artery to a limb is involved the skin beyond the lesion is cold and the peripheral pulses absent. If ischæmia is induced by elevating the limb for some minutes the return of the circulation to the skin on lowering the limb is delayed. When the flush does appear it is usually more intense than on the normal side due to reactive hyperæmia. Occasionally in bilateral disease the skin of the calf is warmer and the leg blood flow is increased on the symptomatically more affected side.

Diagnosis—The disease must be distinguished from other causes of arterial occlusion including generalised atheromatous disease and isolated arterial lesions such as idiopathic thrombosis of the popliteal artery. The finding of obliterative arterial disease with or without gangrene in a male under 50 strongly suggests thrombo-angitis obliterans. The association of arterial disease with superficial painful swellings due to venous thrombosis is diagnostic. Radiological demonstrations of calcified vascular lesions is strong evidence against Buerger's disease as is the finding of a raised blood cholesterol. Lesions restricted to the upper limbs should suggest the possibility of some anatomical abnormality causing compression of the subclavian artery. In an early case diagnosis may be impossible until further scattered venous or arterial lesions appear.

Course and Prognosis—The course of the disease is episodic with recurrent attacks of venous thrombosis, intermittent claudication or gangrene involving several sites in succession. The outcome is unpredictable. Cardiac infarction may cause sudden death early in the disease or the condition may progress steadily over many years with recurrent episodes of thrombosis. Although there may be considerable improvement between attacks due to partial restoration of the circulation some residual disability is usual. In many cases the disease becomes inactive after a succession of attacks.

Treatment—The main disablement results from arterial obstruction. Most of the patients are young adults whose tissues withstand the effects of ischæmia well, and much can be done to avert the loss of a limb. The blocked lengths of arteries usually recanalise and in time a good collateral circulation will form. Treatment, therefore, is chiefly directed to mitigating the effects of ischæmia until the circulation recovers. In acute lesions of the hands or feet the local temperature should be kept low by exposure to cool air. This reduces the metabolic rate and so the need for oxygen. The circulation may be greatly improved by sympatholytic drugs or by sympathetic block. If gangrene occurs treatment should be confined to local excision and pinch grafting under suitable antibiotic cover. When the main disorder is muscle ischæmia the most useful measures are rest and a cool environment. Sympathetic block has little effect on the circulation through muscle and is of little value in these cases. Once the acute stage is past it may be possible to improve the circulation by the production of reactive hyperæmia which stimulates the development of the collateral circulation. For this purpose Buerger's exercises, intermittent venous occlusion or the Pavex boot may be employed.

RAYNAUD'S PHENOMENON

Definition—Intermittent pallor or cyanosis of the extremities brought on by cold with return of skin colour to normal between attacks.

Ætiology—Very great changes in the calibre of the digital vessels occur in normal subjects in response to variations in temperature. The resulting changes in blood flow are greatest in the finger tips (where the blood flow may be a hundred times

greater in the hot finger than in the cold) and diminish progressively towards the wrist. Raynaud's phenomenon is the result of a temporary, complete occlusion of the digital arteries due to an excessive vasoconstrictor response to cold. It may occur in vessels partially obstructed by atheroma or emboli, in scleroderma when the tissue pressure is greatly raised, in the hands of workmen using vibrating tools and it may follow local injury. Syphilitic endarteritis has been recorded as a cause.

Young women frequently suffer from Raynaud's phenomenon. The explanation in these patients was shown by Lewis to be an excessive reaction to cold in otherwise normal vessels. The term Raynaud's disease is usually reserved for this type of digital asphyxia, which is five to ten times commoner in women than in men. In his original description Raynaud included cases of symmetrical gangrene which would now be attributed to organic vascular occlusion or scleroderma.

Symptoms.—Attacks may be brought on by any stimuli which cause digital vasoconstriction. These include handling cold objects, the heat conservation response to a cold environment, sudden fright or emotional tension. In those who work with vibrating tools the attacks are usually brought on by cold but may occur in a warm environment, for example, while in bed. In these patients there are usually signs of sensory loss. In Raynaud's disease the tips of the fingers may be first affected; in scleroderma the phenomenon is often limited to the digits most affected by the collagen disorder.

The colour of the fingers during an attack depends upon the state of venous tone. Commonly it is a pale bluish white, often white with small blue patches. In a prolonged and severe attack the fingers become waxen and shiny. If the spasm relaxes momentarily and the venules fill, the fingers may be deeply cyanosed. In this stage the fingers feel dead and often tingle. If cut, they do not bleed, or only a little dark blood oozes out.

After a period, which may be from a few minutes to 20 minutes or more, the arteries relax and the circulation returns. Pinkish patches begin to appear at the base of the finger, and whole digits become cyanosed. Finally the skin changes to a bright red (reactive hyperæmia) and paresthesiæ are felt. There may be an unpleasant, numb, aching sensation.

Diagnosis.—Raynaud's phenomenon should be distinguished from chilblains, acrocyanosis, erythromelalgia and from the numbness and tingling sometimes found in erythrocyanosis. Diagnosis is certain if immersion of the hands in cold water provokes an attack. When the water is warmed the characteristic changes associated with returning circulation are seen. The localisation to the fingers is characteristic. In early scleroderma Raynaud's phenomenon may be the most prominent feature of the disease. Nevertheless characteristic skin changes are, as a rule, present at this stage, and affect parts of the body other than the fingers. In Raynaud's disease sclerotic changes are usually confined to the fingers and develop only after many years of intermittent digital asphyxia.

Prognosis.—In Raynaud's phenomenon secondary to organic arterial disease the prognosis depends upon the cause. When there is partial obstruction in the digital arteries, for example due to embolism secondary to brachial artery compression, relief of the latter will arrest the condition, but improvement is unlikely. In tool workers the attacks do not occur during work and a change of occupation does not usually prevent attacks; indeed the condition may progress. Raynaud described remissions in young women during pregnancy. In these patients the disease may remit spontaneously for many years, to return at the menopause in a milder form. After several years of severe Raynaud's attacks the fingers become thickened and the skin atrophic, a condition termed *acrosclerosis*. Superficial ulceration of the finger tips is sometimes seen but extensive gangrene of the digits rarely if ever occurs.

Treatment.—Protection against exposure of the hands to cold should be provided by gloves or mittens, and the general vasoconstrictor response to a cold environment prevented by warm clothing. Where occupation or the severity of the disease makes these measures ineffective oral tolazoline hydrochloride (Priscol) may be tried. Where medical treatment fails in Raynaud's disease, cervical sympathectomy is of great value. It prevents reflex vasoconstriction, and keeps the hand warm. Marked local cooling, however, will still provoke attacks. Relapse after sympathectomy is usually associated with return of vasomotor activity. The operation may be repeated with good results.

Superficial ulcers heal slowly and careful treatment with suitable antibiotics is necessary. Sympathectomy may produce dramatic improvement of these trophic lesions, but treatment with vasodilator drugs is often disappointing.

ERYTHROMELALGIA

Definition.—Pain, heat and redness of the extremities due to excessive dilatation of the skin vessels in response to heat, *i.e.* the functional disorder is the reverse of Raynaud's phenomenon.

Symptoms.—The disease may occur at any age but is commonest after middle life. There may be no obvious predisposing factor or the condition may be secondary to organic nervous disease such as spastic paralysis, or to polycythaemia vera. The hands or feet, or both, may be affected and the symptoms usually come on when the patient gets warm in bed or after exercise. The pain is a distressing, burning sensation which may last several hours and relief is only obtained by leaving the feet exposed to the cold air. On examination the skin of the affected parts is red and hot; there may be swelling of the extremities due to vasodilatation.

Diagnosis.—The condition is to be distinguished from other forms of pain and redness of the extremities, so-called erythralgia, in which the skin is cold. This occurs, for example, in arteriosclerotic vascular occlusion and thrombo-angitis. Relief of symptoms by cooling and elevation of the limb is diagnostic. The possibility of some primary cause such as polycythaemia should be investigated.

Treatment.—In an attack the pain is relieved by raising and cooling the affected part. Aspirin often produces considerable benefit. The condition is persistent but leads to no serious complication, hence prophylactic measures are the main form of treatment. Hot environments, over-warm clothing, excessive walking or standing and anything else which provokes vasodilatation must be avoided.

ERYTHROCYANOSIS

Erythrocyanosis crurum puellarum frigida is the full name of this condition. It is a recurrent state of capillary stasis occurring in young girls, affecting the lower limbs, and provoked by exposure to cold. The skin is blue in patches, uniformly cold and there is usually oedema of the ankles. Chilblains are a common association and ulceration may develop. In fact this condition is not separable from chronic pernio. At first attacks occur only in cold weather but later the discoloration and swelling become permanent. The ulcers are painful and take several weeks to heal, leaving behind a brown pigmentation.

Treatment.—Exposure to cold must be minimised and in severe cases it may be worth while to move to a warmer district. Warm clothing, especially woollen stockings, should be worn in cold weather. Exercises and massage may be beneficial. Sympathectomy is not an appropriate form of treatment.

ACROCYANOSIS

Definition.—Persistent cyanosis of the hands, usually in women, without evidence of organic arterial disease.

Ætiology.—The condition is persistent, but is worse in cold weather. The lesion is due to dilatation of the small vessels of the skin, but there is no venous obstruction; hence it has been suggested that the primary fault is increased arteriolar constriction with secondary dilatation of capillaries and venules. There may be a familial incidence.

Symptoms.—The disease is almost entirely confined to women. The fingers are noticed to be cold and blue especially in cold weather. There may be swelling and tenderness but no trophic disturbances occur.

Diagnosis.—The condition is distinguished from erythromelalgia by the coldness of the skin and the fact that pain is inconspicuous. Raynaud's disease differs in the sequence of events during attacks, particularly the pallor due to digital asphyxia. The cyanosis of obliterative arterial disease commonly affects the feet, and the underlying obstructive lesion usually produces other more prominent symptoms or signs.

Treatment.—The condition is benign and the only necessary treatment is protection from the cold.

ARTERIAL EMBOLISM AND THROMBOSIS

Blockage of a systemic artery by an embolus is not usually attributable to primary arterial disease, but is due to detachment of a portion of clot from a thrombus in the heart or a large atheromatous vessel or of vegetations from the heart valves in subacute bacterial endocarditis. In pulmonary embolism (p. 852) the clot is derived from a thrombus in one of the veins of the lower extremity or from the right auricle or right ventricle (mural thrombosis). Very rarely a portion of clot from the right side of the heart may pass to the left side through a septal defect and may cause so-called "paradoxical embolism" in a systemic artery.

The common sites for systemic embolism are the cerebral arteries, especially the middle cerebral (p. 1445), the arteries of the limbs, especially the femoral, and the mesenteric arteries (p. 653). Infarction of the spleen, kidney and retina also occurs.

Femoral embolism is typical of obstruction to the main artery of a limb. The embolus may be detached from the left auricle in a patient with rheumatic carditis after the institution of quinidine therapy for auricular fibrillation or during the stress of labour. Embolism is still an occasional feature of resistant or untreated bacterial endocarditis. In elderly subjects the embolus may be derived from a ventricular mural thrombus secondary to cardiac infarction or chronic heart failure, or from thrombosis in an atheromatous or syphilitic aorta. The onset is usually sudden with acute pain in the limb which rapidly becomes numb, cold and useless. Occasionally the signs of obstruction develop gradually over several hours without much pain. On examination the limb is pale and pulsation is absent below the level of obstruction. Sensation may be lost in a few hours, but hyperæsthesia develops later. If the embolus is not removed gangrene is likely to occur, its extent depending on the age of the patient and the amount of collateral circulation. There is considerable evidence that arterial spasm is induced by embolism and this may be largely responsible for the initial ischæmic symptoms. Relaxation of spasm may be the reason for the gradual improvement which is commonly seen during the first 12 hours, either spontaneously or after treatment by intermittent hyperæmia.

Diagnosis.—The onset of pain in the leg in a patient with cardio-vascular disease should lead to careful examination of the limb for venous thrombosis or arterial

occlusion. The distinction is easy since œdema is prominent in venous thrombosis, the limb is warm and arterial pulsation can usually be felt. Differential diagnosis between arterial thrombosis and embolism depends on the primary disorder. Arteriosclerosis is the common cause of thrombosis and there will usually be evidence of this process elsewhere. Moreover, the popliteal artery is the common site of thrombosis in the lower limb. The symptoms of obstruction are usually less acute and less severe after thrombosis than after embolism, since previous incomplete arterial narrowing will have produced some degree of collateral circulation.

Course and Prognosis.—Most patients may be expected to recover with medical treatment alone; with prompt resort to surgery where necessary gangrene should rarely occur. The prognosis depends very considerably on the age and general condition of the patient. Since severe cardio-vascular disease is usually present, active treatment may be impracticable or death may supervene from other causes.

Treatment.—The patient is nursed in a warm room to encourage vasodilatation. The limb should be kept warm, but not overheated, and great care must be taken to avoid burns from hot-water bottles. The leg should be lowered by blocking the head of the bed. Analgesics are given as required and an attempt may be made to produce vasodilatation by injection of papaverine hydrochloride gr. $\frac{1}{2}$ intravenously. The circulation may be improved by an alternating positive and negative pressure machine (Pavex) or if the obstruction is low enough, by intermittent venous occlusion. Anticoagulant therapy should be given at once, a suitable regime being 50 mg. heparin intravenously every 4 hours and a coumarin derivative by mouth, the dosage being regulated by the prothrombin time. If improvement in the circulation takes place, this treatment is continued for a week. *Should no improvement be observed in 3 or 4 hours*, embolectomy must be undertaken if the patient is in a fit stage to undergo operation. Although embolectomy has been successfully performed up to 24 hours after arterial occlusion, if the patient is seen soon after the onset, operation should not be delayed beyond 12 hours.

Arterial thrombosis is usually a complication of arteriosclerosis or thrombo-angitis obliterans. The femoral, popliteal or posterior tibial arteries may be involved in the lower limb, or the subclavian, axillary, brachial or radial arteries in the upper limb. The symptoms and signs resemble those produced by embolism but the onset is usually more gradual and gangrene is less common and less extensive. Medical treatment as described for arterial embolism should be carried out. Since underlying arterial disease is usually present, operative interference is not advisable if the diagnosis is unequivocal.

NON-SUPPURATIVE (SIMPLE) THROMBOPHLEBITIS.—**Ætiology.**—Simple thrombophlebitis is a not infrequent complication of a variety of conditions which lead to venous stasis. The usual predisposing causes are chronic congestive failure, immobilisation after abdominal operations and childbirth. Thrombophlebitis complicates $\frac{1}{2}$ to 1 per cent. of labours. Hysterectomy and other pelvic operations, herniorrhaphy, gastrectomy, cholecystectomy and splenectomy are the common operations followed by thrombophlebitis. The veins of the calf, the femoral vein or the long saphenous vein are most frequently involved, in that order. It has been assumed that venous stasis due to relative immobilisation is the primary cause of the thrombosis. This is almost certainly not the whole explanation. Other factors such as associated infection, or changes in blood coagulability due to the primary disease or to operative trauma are probably involved, but the exact mechanism is still obscure.

Thrombophlebitis occurs in other conditions where venous stasis is not a prominent feature. It may complicate polycythæmia, leukæmia or carcinomatosis. It may develop in any severe infection, especially typhoid fever. Finally, venous thrombosis is frequently encountered in otherwise healthy subjects who present no evidence of any predisposing factor. In such patients recurrent attacks may occur (thrombophlebitis migrans) and this condition may be so extensive as to produce chronic invalidism.

Pathology.—Venous thrombosis rapidly leads to inflammation of the vein. As a result of invasion by fibroblasts the clot becomes adherent to the vessel wall. The head of the thrombus is composed of leucocytes and fibrin (white thrombus) but the tail is lamellated due to layering of red and white clot. The tail itself becomes firmly adherent in a few hours and detachment to produce embolism rarely occurs after this interval and certainly not after 3 days. Canalsation in the organised thrombus results in partial restoration of blood flow.

Symptoms.—The characteristic picture is seen in so-called femoral thrombosis, in which the obstruction usually involves both external iliac and femoral veins. The whole limb becomes swelled; pain is variable and not usually conspicuous. There is congestion of superficial veins and frequently the thrombosed vein may be palpated as a tender, hard cord. Fever, malaise and tachycardia may be present at the onset. Thrombophlebitis secondary to abdominal operation usually starts in the deep veins of the calf and is observed between the fourth and fourteenth post-operative days in most cases. Local tenderness may be the only sign, although the circumference of the calf may be increased due to œdema. Passive dorsiflexion of the foot may elicit pain in the absence of other signs.

Thrombosis of the axillary or subclavian vein produces similar changes in the upper limb.

Thrombosis of the inferior vena cava may occur under the same conditions as peripheral vein thrombosis. Special causes are the pressure of abdominal masses such as liver abscess, ascites or retroperitoneal tumours, or thrombophlebitis migrans extending from the femoral veins. Swelling of both legs may be present due to associated iliac or femoral thrombosis. Distension of the venous collaterals over the lower abdomen develops later.

Diagnosis.—The early diagnosis of thrombosis of the calf veins after operation, described above, is particularly important. In cases without obvious precipitating cause full investigation is essential to rule out any underlying lesion, such as pelvic carcinoma involving the iliac veins or abdominal neoplasms compressing the inferior vena cava.

Course and Prognosis.—In the uncomplicated case œdema, pain and constitutional signs subside in 2 to 3 weeks and recovery is complete. Pulmonary embolism is the most serious complication of thrombophlebitis (p. 852). Chronic venous obstruction may follow femoral or axillary vein thrombosis, the chief manifestations being persistent or recurrent œdema and aching pain in the limb when standing or

Degenerative lesions causing arterial aneurysms are atheroma and mucoid degeneration of the media. Atheroma produces a uniform dilatation of the aorta (so-called fusiform aneurysm) which commonly affects the ascending aorta, arch and descending thoracic aorta. Simple atheromatous dilatation of the abdominal aorta is not uncommon but true aneurysm formation, with the production of a large saccular tumour and painful erosion of the vertebral bodies, is always syphilitic. Medial degeneration is the usual cause of dissecting aneurysm.

DISSECTING ANEURYSM OF THE AORTA

Incidence.—Dissecting aneurysm is a not uncommon cause of sudden death. The subjects are almost always elderly and the incidence is reported to be five times as high in men as in women.

Ætiology and Pathology.—The primary cause is mucoid degeneration of the media. Atheroma is invariably present but is not itself a cause of dissecting aneurysm. The dissection occurs down the centre of the medial coat, forming a false channel between the two layers. The tear usually starts in the ascending aorta, less commonly in the descending thoracic or abdominal aorta. By rapid extension the aneurysm may reach the bifurcation of the aorta, occluding one or both renal arteries *en route*. Extension towards the heart may lead to rupture into the pericardium and sudden death. External rupture into the mediastinal or retroperitoneal tissues is less common. Very rarely the dissection may be arrested before any main arteries are involved and over a period of years there may be recurrent attacks. In most cases, however, death occurs in the first attack.

Symptoms.—The common presenting symptom is agonising pain in the abdomen, chest or back together with shock. The pain is persistent and may change in site as the dissection spreads. Obstruction of the renal vessels leads to pain in the loins and anuria. Occlusion of one or both common iliac arteries produces pain, numbness or coldness of the affected extremity. The patient is grey and collapsed, the pulse rapid and small, but the blood pressure is often maintained, hypertension being present in many cases. Involvement of the carotid or spinal arteries may produce paralysis, or the limbs may be pulseless and cold due to arterial obstruction. There may be some degree of improvement for a few hours, after which rupture into the pericardium may lead to a sudden attack of pain in the chest and fatal collapse.

Diagnosis.—The condition is most commonly mistaken for coronary thrombosis or an acute abdominal emergency such as perforation of a peptic ulcer. Diagnosis can only be made with certainty if signs of occlusion of specific arteries, e.g. renal, femoral, spinal or carotid can be detected. More often the diagnosis may be suspected in life but is only confirmed post mortem. There is no effective treatment.

COLLAGEN DISEASES

The term collagen disease was first used by Klemperer in 1942 to describe a group of disorders which had in common a general disturbance of connective tissue. This involved in particular the extracellular components of connective tissue, the collagen fibres and so-called ground substance. Included in this group are rheumatic fever, rheumatoid arthritis, polyarteritis nodosa, disseminated lupus erythematosus, generalised scleroderma and dermatomyositis. These conditions all show in different degree changes in connective tissue including fibrinoid degeneration of collagen, excessive deposition of collagen, increase and alteration in ground substance, proliferation of connective tissue with or without degenerative change and inflammatory cell infiltration.

tion The conditions are distinguished pathologically by the degree and distribution of these particular changes

Clinically as well as histologically these diseases have much in common and there are many cases which cannot be allocated to one or the other, but form a transitional picture between the various disorders The pathogenesis in most instances is not clear, although there is evidence in some of the diseases of an allergic reaction to bacterial antigen This is the case in polyarteritis nodosa In disseminated lupus, evidence of abnormal antibodies in the circulation and hyperglobinæmia also suggest some abnormal antigen antibody reaction Polyarteritis nodosa, temporal arteritis, disseminated lupus, scleroderma and dermatomyositis are discussed here Rheumatic fever and rheumatoid arthritis are dealt with elsewhere

POLYARTERITIS NODOSA

Synonym —Periarteritis Nodosa

Definition —A disease in which widespread acute necrosis occurs in the arteries leading to a variety of functional disturbances involving the nervous system, heart, kidneys, lungs, blood and abdominal viscera

Incidence —The condition may occur at any age, though the maximum incidence is between 20 and 30 years Males are affected three times as often as females

Ætiology and Pathology —The condition may be regarded as an allergic or hypersensitivity reaction to a bacterial antigen In a considerable proportion of cases bacterial infection, particularly due to streptococci, precedes the onset of the disease More recently polyarteritis nodosa has resulted from hypersensitivity to drugs (sulphonamides) and foreign proteins The arterial lesions consist of necrosis with inflammatory reaction involving all coats of the arteries (pan arteritis) There is great swelling in the intima, necrosis of the media may lead to aneurysm formation and even rupture Intense inflammatory reaction of the adventitia (periarteritis) results Obstruction of the lumen by thrombosis is common Medium sized and large vessels are characteristically affected, but arteriolar lesions may appear, especially in the viscera The vascular lesions are essentially focal The common sites for arterial necrosis are the kidney, abdominal viscera (pancreas, intestines, spleen, liver, gall bladder, testis, mesentery), peripheral vessels, coronary arteries, cerebral arteries and rarely the pulmonary vessels The disease is episodic, phases of activity being followed by periods of quiescence with healing of the vascular lesions Organisation of the inflamed segments results in asymmetrical intimal thickening (endarteritis) with fibrosis in the other arterial coats Pathological changes in the tissues such as infarction, hæmorrhage and peripheral nerve degeneration are the result of vascular necrosis or thrombosis There is also severe anæmia and intense pulmonary œdema in the terminal stages Diffuse glomerular nephritis may be an associated lesion

Symptoms —The clinical manifestations are protean and all systems may be involved The following are the common methods of presentation

(1) Continued, irregular, unexplained fever These patients present with malaise, loss of weight, progressive anæmia, muscle pains and general misery

(2) Polyneuritis, either local or symmetrical, may be the mode of onset and polyarteritis nodosa should be suspected in unexplained cases of wrist drop or foot drop associated with fever and anæmia

(3) The patient may present with hæmorrhage, either abdominal due to a ruptured aneurysm cerebral or renal

(4) Paroxysmal attacks of bronchial asthma with transient non specific pneumonitis

(5) Occasionally, the mode of onset resembles some other disease, there may be polyarthritis suggestive of rheumatoid arthritis or a typical attack of acute diffuse nephritis or the development of malignant hypertension

walking. Chronic venous distension leads to varicosities and varicose ulceration. Induration of the limb due to persistent œdema and recurrent cellulitis may produce lymphatic obstruction which greatly aggravates the swelling and further impairs the nutritional state of the tissues. Obesity, varicose veins and inadequate treatment in the early stages predispose to chronic venous obstruction.

Treatment.—Preventive measures against post-operative thrombophlebitis include early ambulation, leg exercises and massage, avoidance of tight bandages and pressure on the calves, and the adequate treatment of dehydration and infection. After operation and in congestive heart failure anticoagulant therapy, as described on p. 847, is given at the earliest intimation of venous thrombosis to prevent extension and pulmonary embolism. Ligation of the femoral vein or even of the inferior vena cava has been performed as a prophylactic measure against pulmonary embolism after thrombophlebitis has occurred, but these measures have not been justified by the results.

In the treatment of femoral thrombosis the patient should be kept at rest in bed until all œdema, tenderness and constitutional signs have subsided. The limb should be elevated to about 30° on an inclined plane. Hot fomentations may be applied to the limb if there is evidence of secondary vasoconstriction. Analgesics are given as required. After 3 days, active movements at all joints are encouraged. Should there be any return of œdema when the patient is allowed up, knee-length elastic stockings should be fitted; these are worn during the day and removed at night until the venous circulation returns to normal.

THROMBOPHLEBITIS MIGRANS—This condition has already been mentioned as a recurrent form of idiopathic thrombophlebitis. Attacks of venous thrombosis occur over a number of years and the veins of the legs, arms, trunk and the inferior vena cava may be involved. Chronic venous congestion of the legs may lead to widespread varicosities and indolent ulceration. The cause is unknown and no effective treatment is available. In a rapidly progressive case it may be justifiable to give a course of anticoagulant therapy, but this is only a temporary measure and does not halt the progress of the disease.

Diagnosis.—Although pitting œdema is usually present, lymphœdema has a characteristic solid or brawny consistency due to its chronicity, which leads to proliferation of connective tissue and inflammatory fibrosis. The age and circumstances of onset, rate of development and presence or absence of primary lymphangitis make the diagnosis of the cause fairly obvious.

Prognosis.—Lymphœdema is a chronic disorder which increases gradually or by successive attacks according to the ætiology. Although partial remissions occur in the early stages, irreversible changes due to inflammation and connective tissue thickening eventually lead to permanent enlargement of the limb. Recurrent attacks of cellulitis and ulceration are then liable to aggravate the symptoms still further.

Treatment.—Attempts should be made to reduce the œdema by elevation of the limb and elastic bandaging. A well-fitting elastic stocking may keep the swelling down in less severe cases. If lymphangitis, cellulitis and ulceration are present every effort must be made to reduce œdema; the infection is treated by appropriate antibiotics and local application of a non-adherent (oily) dressing. Hereditary lymphœdema, if severely disabling, is best treated by superficial lymphangiectomy, the œdematous subcutaneous tissue being removed and the muscles covered with free skin grafts.

ARTERIAL ANEURYSM

An aneurysm is a permanent dilatation of an artery due to destruction of its wall. Since the strength of the arterial wall lies in the muscular or musculo-elastic tissue of the medial coat the causes of aneurysm formation are pathological lesions affecting the media. These may be congenital, traumatic, inflammatory or degenerative.

Congenital aneurysm is almost entirely confined to the arteries at the base of the brain. The cause is a congenital defect of the media, leading to the formation of a "berry" aneurysm usually at some point on the circle of Willis. More than one aneurysm may be present. Pressure effects due to enlargement of the sac, and rupture, leading to intracerebral or subarachnoid hæmorrhage, are responsible for the various clinical manifestations (p. 1447). The so-called cirroid aneurysm is a developmental anomaly in which greatly dilated arteriovenous communications form a large vascular tumour, particularly in the brain.

Traumatic aneurysm.—This results from a penetrating injury, commonly a gunshot wound, which injures a main artery and gives rise to aneurysmal swelling. The sac may connect with the neighbouring vein, producing a so-called arteriovenous aneurysm. The main arteries of the limbs, especially the popliteal, are most frequently affected. A bruit is commonly heard over the sac. If an arteriovenous fistula is large, the pulse may be collapsing and increased cardiac output leads to cardiac enlargement. Treatment lies in closing the anastomosis and restoring continuity of the artery by local excision or grafting.

Inflammatory causes.—The common inflammations producing aneurysms are syphilis, bacterial endocarditis and periarteritis nodosa. The last may affect any artery, particularly the abdominal branches of the aorta, the cerebral and the limb arteries (p. 931). Syphilitic aneurysms are almost entirely confined to the aorta and its large branches (p. 858). Mycotic aneurysms in bacterial endocarditis are due to blockage of arteries by infected emboli arising from valvular vegetations. The femoral, brachial, retinal and cerebral arteries are particularly affected. Rupture of the last causes subarachnoid hæmorrhage. Mycotic aneurysms are becoming less common as a result of antibiotic therapy but may still arise when the causative organism is resistant to antibiotic control. Rupture of a mycotic aneurysm in a limb vessel may produce a large intramuscular hæmatoma, followed by great pain and swelling of the limb and even gangrene. Surgical release of tension by evacuation of clot may be necessary.

Signs—Fever, tachycardia, wasting and anaemia are common to all forms. The temperature is irregular and moderately raised, but in severe cases may be very high. The general attitude of the patient, particularly in the later stages, is one of progressive depression and misery. Subcutaneous nodules may occasionally be discovered along the course of small arteries in the limbs or in the abdominal wall. Skin rashes are common and include purpura, urticaria and macular or maculo-papular erythema. Joints may show evidence of acute arthritis. There may be signs of pulmonary congestion and oedema and there is sometimes a marked element of bronchospasm. Hypertension is often absent in the early stages but with the appearance of renal involvement there is usually a moderate rise in blood pressure, very occasionally malignant hypertension develops during the course of the disease. Heart failure is a frequent late complication.

Abdominal signs are often vague but may be due to haemorrhage, perforation of the gut, or involvement of the gall bladder or appendix by vascular lesions. Peripheral neuritis may be present as a 'mononeuritis multiplex' or as symmetrical polyneuritis, cerebral lesions such as thrombosis or rupture of an aneurysm may lead to focal paralyses of wide variety. The kidneys are usually involved at some stage of the disease and albuminuria and haematuria are common. Rapid renal failure may develop as a result of progressive occlusion of the renal vessels.

Examination of the blood shows polymorphonuclear leucocytosis in 70 per cent. of cases and eosinophilia in less than one fifth. The sedimentation rate is raised. Anaemia is nearly always present and is often severe.

Diagnosis—If a subcutaneous nodule is discovered it should be removed for histological examination, otherwise diagnostic muscle biopsy should be carried out, as large a piece of muscle as possible being removed. Typical arterial necroses are found in the majority of cases by this technique. The differential diagnosis includes a wide variety of conditions particularly other cause of obscure fever, nephritis, malignant hypertension, other forms of polyneuritis, cerebrovascular disease and other collagen disorders. Diagnostic proof depends on the demonstration of the typical acute or chronic pathological changes in the arteries.

Course and Prognosis.—Phases of activity alternate with remissions during which the patient may be afebrile and free from symptoms. Occasionally recovery occurs spontaneously from a focal attack, e.g. a vascular lesion in the appendix or gall bladder, and after an interval of perhaps a year the symptoms of generalised polyarteritis appear. In the absence of treatment the majority of patients run a progressive course terminating in renal failure, haemorrhage, pulmonary oedema or cerebrovascular accident.

Treatment.—Cortisone or corticotrophin offer the only possible effective treatment. The use of these drugs is followed by prompt remission of fever with relief of symptoms and recovery of anaemia. Renal, cardiac or neurological damage may be arrested, but many of the results of vascular necrosis are irreversible. Cortisone may be used continuously or may be discontinued during remissions and resumed in full doses (100 to 300 mg. daily by mouth) whenever a relapse occurs. The ultimate outcome of this form of therapy is uncertain but it is apparent that the hormone may modify the disease in the active phases by preventing vascular complications, so that life may undoubtedly be prolonged.

TEMPORAL ARTERITIS

This condition was first described by Jonathan Hutchinson in 1890. It is an affliction of elderly subjects, usually over the age of 60, and the incidence is the same in both sexes.

Aetiology and Pathology—The pathological process so closely resembles polyarteritis nodosa that a similar pathogenesis seems likely, but evidence of any pre-

precipitating factor is lacking. The lesion may be localised to one segment of the temporal artery or may extend along the vessel producing obstruction at several points. Histologically there is organised thrombosis, intimal proliferation, medial necrosis with giant cell reaction and adventitial inflammatory infiltration. Other arteries, including the cerebral, retinal and peripheral vessels, are occasionally similarly involved.

Symptoms.—These are general and local. There may be fever, malaise, anorexia, weakness, weight loss, night sweats and progressive anaemia as in polyarteritis nodosa. Pain over the temporal artery is a constant feature and may be associated with severe generalised headache. Involvement of other arteries may produce various symptoms such as impairment of vision or cranial nerve palsies. On examination there is tenderness over the inflamed artery, which is usually prominent, hard and nodular; pulsation may be absent; both temporal arteries may be affected. Blood examination shows an anaemia with variable leucocytosis and elevated sedimentation rate.

Prognosis.—The condition usually improves gradually and completely over the course of several months, although obliteration of the arteries is permanent. Relapses occasionally occur.

Treatment.—The majority recover without any residual disability. In view of the possibility of permanent visual impairment or paralysis when the retinal or cerebral vessels are involved, cortisone therapy may be tried in severe cases. Favourable results after this form of treatment have been reported.

DISSEMINATED LUPUS ERYTHEMATOSUS

Definition.—A diffuse disease of connective tissue characterised by a variable combination of the following manifestations: fever, increased sedimentation rate, symmetrical erythema, visceral lesions, hyperglobulinæmia and a specific serum factor which produces abnormal phagocytosis in leucocytes.

Incidence.—Eighty to 90 per cent. of cases are women of child-bearing age, but before puberty the sex incidence is equal.

Ætiology and Pathology.—The ætiology is unknown but various factors which may exacerbate the disease suggest the presence of a bacterial or chemical hypersensitivity reaction. Such factors are infection, drugs (especially sulphonamides), sunburn, exposure to X-rays or injection of foreign proteins. There are certain elements in the picture such as glomerular and arteriolar lesions in the kidney, polyarthritides and the episodic nature of the disease which relate it to other collagen disorders. Pathologically there is widespread involvement of the connective tissues although it is difficult to define any specific histological lesion. Fibrinoid necrosis of arterioles may be widespread in the viscera and there is fibrinoid change in collagen with increase in ground substance, particularly in serous membranes, synovial membrane, endocardium (so-called verrucous endocarditis), lymph glands, spleen and skin. Thickening of the capillary basement membrane of the renal glomeruli presents a characteristic wire-loop appearance. Pneumonitis, pleural effusions and hepatitis may be present.

Symptoms.—The course of the disease is one of remissions and relapses which may prove fatal in a few months or may continue for many years. Acute, subacute and chronic forms have been described but these courses merge into one another and merely reflect the great variations in intensity of the disorder. The name disseminated lupus over-emphasises the importance of the skin lesion which is variable in character and distribution and may be absent. In about one-fifth of the cases the disseminated lesion develops on a pre-existing discoid lupus. The characteristic picture is a red, slightly raised, sometimes oedematous eruption affecting particularly exposed areas, i.e. the backs of the hands and upper part of the front of the chest, with a butterfly distribution on the face. The rash may, however, be pleomorphic

or purpuric and splinter hæmorrhages of the nails are sometimes seen. There may be a low-grade, irregular fever or a swinging temperature, according to the intensity of the disease. Tachycardia, wasting and progressive anæmia are usual. Many cases present with obvious polyarthritis resembling rheumatoid arthritis; the fingers are particularly affected and are often cold and blue, suggesting Raynaud's phenomenon. The joint condition may be transient like that of rheumatic fever or more acutely inflammatory like infective polyarthritis; sometimes there is persistent severe joint pain with little objective change. Verrucous endocarditis produces few if any clinical signs in the heart although a systolic murmur may be due to organic mitral disease. Heart failure is usually a late development but isolated cardiac involvement, without other manifestations of the disease, has been described. Pericarditis is not infrequent. Dyspnoea is a prominent symptom and may be extreme in the early acute case; the usual cause is acute pulmonary congestion or a pneumonitis resembling "rheumatic pneumonia". Pleurisy with a small or moderate effusion often develops and pleuritic pain is a common complaint. A variety of lesions may appear in the abdominal viscera. The spleen is frequently enlarged and this may be associated with generalised enlargement of superficial lymph glands; both may subside dramatically when the temperature falls during a remission. Hepatitis may occur at any stage of the disease and clinically may differ from infective hepatitis only in the persistent high temperature. Abdominal pain, nausea, vomiting and diarrhoea and even gastro-intestinal hæmorrhage may occur, but are not common. Albuminuria indicates the development of glomerulonephritis which is an irreversible lesion and eventually leads to uræmia. The mental state of the patient is often labile, psychotic changes are common, and convulsions occur in about a quarter of the cases; both these may be presenting symptoms. The optic fundi occasionally show exudates, hæmorrhages or even papilloedema.

Special investigations are of great value in diagnosis. The blood sedimentation rate is always raised and often exceeds 100 mm. (Westergren). Hyperglobulinæmia is almost always present and at some stage there is a leucopenia with a total white count less than 5000 per c.mm. The anæmia may be non-specific and normocytic or hæmolytic, and platelets may be reduced. The serum should always be examined for the "L.E. phenomenon", which is positive in the great majority of cases. If serum from a patient with lupus erythematosus is incubated with leucocytes (from his own or from normal blood) characteristic inclusions appear in the cytoplasm of the polymorphonuclear leucocytes. These bodies are depolymerised desoxyribonucleic acid, presumably of nuclear origin. The *in vitro* phagocytosis of such inclusions is dependent on a gamma globulin fraction of the plasma proteins, possibly antibody in nature. More recently phagocytosis of this material has been shown to depend on an additional factor derived from platelet breakdown. These "L.E." cells are characteristic of the disease but are not entirely specific since the phenomenon has been observed in patients sensitised to penicillin and other drugs. The abnormal plasma globulin may produce a "false" positive Wassermann reaction (in about 20 per cent. of cases), which can be distinguished from a true positive by the treponema immobilisation test. Recent work has shown that an appreciable proportion of Wassermann tests carried out routinely give this false positive reaction and the L.E. phenomenon may be present in a small number of these cases; clinical manifestations resembling disseminated lupus may develop. Other patients with a false positive W.R. may subsequently suffer from a variety of symptoms whose relation to disseminated lupus is not yet clearly understood.

Diagnosis.—This depends on the association of the various clinical features described above with increased sedimentation rate, hyperglobulinæmia and the presence of the L.E. cell factor in the serum.

Course and Prognosis.—In fulminating cases death may occur from exhaustion, toxæmia, infection or convulsions after a few months. Most cases exhibit remissions

and relapses for several years and a few run a very chronic course. Where the condition follows discoid lupus the course is less severe and the outcome more favourable. The appearance of albuminuria is a bad prognostic sign.

Treatment.—Cortisone or corticotrophin are the only drugs which offer any possibility of controlling the disorder. In the active stage cortisone in adequate dosage produces prompt fall in temperature, subjective improvement, resolution of the rash and improvement in joint signs and pulmonary symptoms. The L.E. phenomenon often persists even though a full clinical remission follows treatment. The current practice is to raise the daily dose of cortisone rapidly (up to 400 mg. or more) until fever is controlled, and then to lower it gradually to a satisfactory maintenance dose. In severe cases the typical facies of Cushing's syndrome may be expected to develop before control is adequate and remission occurs. The appearance of psychotic changes or convulsions should not lead to discontinuance of treatment. A low sodium diet should be given together with potassium chloride to prevent salt retention and hypopotassemia; œdema may develop in spite of low salt intake and is best treated by intramuscular injection of mercurial diuretics. Secondary infection is a serious hazard during cortisone therapy and appropriate antibiotics (not sulphonamides) should be given at the first sign of this complication. The treatment of disseminated lupus with cortisone is at present under extensive trial. Although a dramatic remission may be observed during an acute attack there is no improvement in the renal lesion once it has occurred, nor is there yet evidence that complete recovery may be produced.

GENERALISED SCLERODERMA

Definition.—A widespread disorder of connective tissue and blood vessels producing a progressive thickening of the skin and subcutaneous tissues. The heart, lungs, kidneys and other viscera may be involved.

Ætiology and Pathology.—The disease affects women more often than men, the usual age of onset being 30 to 50. No definite cause or precipitating factor is recognised. Occasionally circumscribed scleroderma (morphœa) may develop into the generalised disease. Histologically there is great increase and thickening of collagen fibres, with slight fibrinoid change, affecting the skin, lungs, heart, gastrointestinal tract and joints. Some degree of atrophy and lymphocytic infiltration of skeletal muscle is found. Endarteritis obliterans occurs in the affected organs and severe fibrinoid necrosis of the glomerular arterioles may lead to renal failure.

Symptoms.—The disease commonly presents with swelling of the fingers, hands and face. The features become immobile and expressionless, the fingers pale and blue, and frequently the typical Raynaud phenomenon occurs with minimal scleroderma. As the process develops the skin is at first tense and swollen, then becomes stiff, hard and adherent to deep structures; finally, general tissue atrophy produces the fully developed picture to which the names acrosclerosis and sclerodactyly have been given. Ulceration of the finger-tips is usual in this stage and may be followed by gangrene of the fingers, which tends to be bilateral. The process may spread over the trunk and lower limbs and there may be extensive calcification in the sclerotic areas. Pigmentation of the skin is usually present and melano-leukodermia is sometimes seen. The joints are often stiff and painful and the muscles become weak and atrophied. Visceral involvement should always be looked for. Involvement of the œsophagus causes dysphagia due to loss of peristalsis and to the development of stenosis at the lower end. The heart is less commonly affected, but pericarditis or cardiac enlargement may be present and myocardial fibrosis may lead to heart failure. The electrocardiogram may show partial A.V. block with low voltage in the absence of clinical signs. Fibrosis of the lungs and bronchi may cause cough and dyspnoea. After albuminuria appears, acute arteriolar and glomerular necroses in the kidneys

are apt to lead to the rapid development of uræmia without hypertension. Fever is present only in those cases which come on acutely; weakness and exhaustion occur in the chronic stages. Apart from the specific changes due to visceral lesions, special investigations reveal little of note except elevation of sedimentation rate and variable anæmia.

Diagnosis.—Raynaud's phenomenon occurs early in scleroderma and the distinction from Raynaud's disease rests on the presence of thickening of the skin in sites other than the fingers, e.g. on the face or trunk. Acrosclerosis occurs late in Raynaud's disease and it is always confined to the areas of digital asphyxia. Skin biopsy shows no specific histological changes; in the early stages there is œdema and perivascular infiltration, in the later stages, great increase in collagen.

Course and Prognosis.—Spontaneous recovery is very rare. Occasionally the disease runs an acute course with fever, marked constitutional changes and death from heart failure or secondary infection within a few weeks or months. In general, however, the onset is insidious and the course slowly progressive over a number of years. The later stages are often distressing as the patient becomes immobilised by the increasing rigidity of the skin and subcutaneous tissues. Fixation of the chest may lead to broncho-pneumonia. Uræmia, myocardial failure and inanition due to dysphagia may all contribute to the fatal outcome.

Treatment.—There is no effective specific therapy. Sympathectomy may relieve symptoms due to the Raynaud phenomenon in the hands or feet, but the symptoms usually returns after an interval of a year or less. Improvement with cortisone or corticotrophin therapy has been reported but in chronic scleroderma little more than slight subjective benefit can be expected.

DERMATOMYOSITIS

Definition.—A connective tissue disorder in which muscle necrosis is the most prominent feature, with increase in collagen in the skin, joints and viscera.

Ætiology and Pathology.—The borderline between scleroderma and dermatomyositis is ill-defined and both may be varieties of the same collagen disorder. The age of onset is usually between 10 and 50, the distribution is equal between the sexes, and there is no known ætiological factor apart from a possible association with malignant tumours. Histologically there is great increase and thickening of collagen fibres, with slight fibrinoid change in skin, joints and heart as in scleroderma. The affected skeletal muscles show severe necrosis with inflammatory cell infiltration.

Symptoms.—The onset may be sudden or insidious and the disease may be rapidly fatal or may run a chronic course with frequent remissions and relapses. Presenting symptoms are weakness, stiffness and aching pain in the muscles, involvement of which is usually bilateral and symmetrical. Fever is present in the acute phases. Weakness may be so extensive and severe as to suggest acute polyneuritis. Later, muscular atrophy occurs and contractures may develop. Involvement of the muscles of the larynx and pharynx may produce difficulty in talking and coughing, dysphagia and nasal regurgitation. Weakness of the diaphragm and intercostal muscles may lead to respiratory failure. Joint changes, with stiffness and peri-articular swelling, particularly affecting the fingers, resemble rheumatoid arthritis. An erythematous rash on the face and arms is common in the early stages and there may be œdema of the eyelids and hands. Thickening of the skin, as in scleroderma, may follow. Cardiac involvement is unusual except as a terminal event, but there may be electrocardiographic evidence of myocardial damage at an earlier stage.

Examination of the blood usually shows some elevation in sedimentation rate, and in the acute stage a considerable polymorphonuclear leucocytosis may be present. The urine sometimes contains albumin and always a marked excess of creatine.

Muscle biopsy reveals diagnostic changes in the form of muscle necrosis and inflammatory cell reaction.

Diagnosis.—The differentiation from scleroderma is impossible in some cases without muscle biopsy. In a severe acute attack polyneuritis may be suspected, but the absence of sensory changes, the pain and tenderness of the muscles and the finding of an erythematous rash or œdema of the face should make the diagnosis clear; if doubt remains, a positive muscle biopsy is conclusive.

Treatment.—In the acute stages cortisone or corticotrophin may produce a prompt and sustained remission. Special precautions should be taken to prevent respiratory infection and to deal with respiratory paralysis should it appear. In the chronic stages of the disease little benefit can be expected from hormone therapy.

CLIFFORD WILSON.

SECTION XIII

DISEASES OF THE RESPIRATORY SYSTEM

DISEASES OF THE NOSE

ACUTE CATARRHAL RHINITIS

(See The Common Cold, p 147)

EPISTAXIS

Ætiology—The causes of epistaxis may be classified as follows

Local causes—Trauma, including blows on the nose, fracture of the base of the skull, surgical operations and foreign bodies, small septal erosions, atrophic rhinitis when crusts separate, malignant disease, "bleeding polypus" of the septum and hereditary hæmorrhagic telangiectasia. Epistaxis may be an early symptom of leprosy.

General causes—Hypertension, chronic nephritis, cirrhosis of the liver, violent exertion, extremes of heat and cold, congestion at the menstrual period or "vicarious menstruation", venous congestion, as in mitral stenosis, tumours in the thorax or root of the neck, emphysema, bronchitis and whooping cough, blood conditions such as pernicious anæmia, leukæmia, purpura, scurvy and all the acute infectious fevers especially in the prodromal stage. To these may be added rarefaction of the air, as in aeroplane ascents and mountaineering, and poisoning by some drugs, especially salicylates and quinine.

The source of the bleeding is, in the large majority of cases, in a region called Little's or Kiesselbach's area, situated on the front and lower part of the septum just beyond the vestibule.

Treatment—Severe epistaxis should always be treated, though it is of comparatively little importance in healthy young people. In older patients with high blood pressure the loss of blood may be beneficial, but the occurrence is so distressing and alarming to the patient that steps must be taken to control the bleeding. It is wrong to lay patients down, they should be propped up in bed with the head inclined slightly forward so that blood cannot enter the pharynx and larynx and add to their embarrassment.

The source of the bleeding is usually so far forward that a pledget of wool introduced for less than an inch into the naris, and held by compressing the nostril, will generally control it temporarily. To arrest it and prevent recurrence the bleeding spot must be found, controlled by application of cocaine and adrenaline on a plug of wool, and sealed by the galvano-cautery at dull red heat. In obstinate cases the bleeding may recur from another spot or from the opposite naris, when the treatment must be repeated. As in other forms of hæmorrhage, a rapid, excited heart's action, associated with restlessness and fright, is often present, and an injection of morphine is of great value. If the bleeding is from the usual situation, formal plugging of the nose is seldom called for, but sometimes it is so profuse or the bleeding point is so far back that its situation cannot at first be determined. In such cases the naris should be evenly packed with ribbon gauze introduced on forceps under direct vision. The older method of plugging the posterior naris is seldom required, and carries the risk of causing otitis media. Nasal plugs quickly become septic, and should ordinarily be removed in 24 hours, but if ribbon gauze impregnated with sulphanilamide powder is used this may safely be left *in situ* for 3 days.

ALLERGIC RHINITIS

Ætiology.—This is among the commonest and most obvious manifestations of allergy. As in other examples of this condition, the patient is susceptible to very minute doses of some substance, usually a protein, to which he has become sensitised but to which normal people are completely immune. It is thought that histamine or some closely allied substance is liberated which by altering cell permeability causes mucosal swelling. The substances which may cause allergic symptoms are numerous and diverse, and enter the body by various routes:

A. By inhalation: 1. Vegetable particles: the pollen of certain plants, especially grasses; powdered orris-root, until recently a component of toilet powders; moulds, especially dry-rot and the spores of some fungi; and even the scent of such flowers as roses, though here association probably has a psychological effect. 2. Animal emanations: the dandruff of animals, horses, cats, dogs and others; the feathers of poultry, which have their chief opportunity of acting when used to fill pillows and mattresses. 3. House dust, which may contain any of the above substances.

B. By ingestion: Numerous common and uncommon articles of diet, such as eggs, strawberries and fish, especially shell-fish, may produce allergic sensitisation; the rhinorrhœa and skin-eruptions caused by the iodides and some other drugs may be of allergic origin.

C. From a focus of infection, most often from disease of the paranasal sinuses.

The affection is distinctly hereditary and is often associated, either in the patient or his relations, with such other symptoms of allergy as asthma, urticaria, angioneurotic œdema or chilblains. It often shows itself in early adolescence and tends to improve with advancing age, though it is not unusual for symptoms to commence in the second or third decade. Males and females are equally affected. It is most frequent among the upper classes. A mental shock is sometimes the starting-point of the attacks, and a psychogenic influence is often apparent.

Symptoms.—The nasal mucosa is swollen, pale and waterlogged. Fits of sneezing are associated with profuse watery discharge, irritation of the nasal and conjunctival mucous membrane, and often much depression and prostration. The nasal airway may become almost completely obstructed, and this is liable to happen when the patient enters a hot, stuffy room. Sudden clearing of the obstruction may occur when he goes out into the open air. The rapidity with which the symptoms come and go is sufficient to distinguish them from the ordinary coryza. The predominating cells found on examining a nasal smear are eosinophils, and eosinophilia is often evident on blood examination.

Sensitisation to pollen is the commonest variety of allergic rhinitis, and is known as "hay-fever"; it is seasonal and, when caused by the pollen of grasses, the attacks begin about the end of May and cease in August, and those due to beather continue a few weeks longer.

Treatment.—The determining factors, which should receive attention, are heightened irritability of the nervous system, occasionally some intranasal abnormality which increases the sensitiveness, and the specific irritant. Hay-fever patients are better in a locality as free as possible from pollen; some remain comparatively well at the seaside, others only on board ship and a few have to spend the best days of the year in a darkened room. It is only rarely that benefit results from correction of some nasal anatomical abnormality; indeed, surgical treatment is only of real value when polypi in the ethmoid region cause so much crowding that nasal obstruction is almost complete (chronic nasal œdema). Cauterisation of the so-called sensitive areas, which comprise the septal mucosa opposite the middle turbinate and the mucosa on the anterior end of inferior turbinate gives but temporary relief in a small proportion of cases. Ionisation of the nasal mucosa with sulphate of zinc is also

employed True hay-fever patients may have their susceptibility to pollen lessened by inoculation with dilute extract of pollen, the use of these extracts gives excellent results in a proportion of cases, and attempts are being made with varying success to test susceptibility to, and to immunise against, other proteid poisons The antihistamine drugs must take their place in the symptomatic treatment of allergic rhinitis. Though they do not cure the condition they are of value in alleviating severe nasal obstruction This is especially the case when dealing with seasonal allergy (hay fever), phenindamine (Thephorin) 25 mg may be given in the morning and promethazine (Phenergan) 25 mg in the evening These drugs are much less effective in cases of perennial nasal allergy The conjunctivitis often needs attention, a simple lotion may be used with an eye bath or as drops acid borici gr 4, zinci sulph gr $\frac{1}{2}$, aqua dest to fl oz 1, 1 drop of adrenaline, 1 in 1000, also gives great though transient relief Dark glasses, too, are very helpful

ACCESSORY-SINUS SUPPURATION

Ætiology—In the large majority of cases infection reaches the accessory sinuses from the nasal cavity, and may result from a simple coryza or from one of the acute infectious fevers Influenza is especially liable to produce disease of the sinuses. Badly maintained swimming baths are often responsible for initiating the disease. In addition, antral suppuration is caused by infection from the teeth particularly the second bicuspid and first two molars, whose roots are in closest proximity to the antral floor When one sinus becomes infected, spread to other sinuses is to be expected if appropriate measures are not taken in the early stages

Symptoms and Diagnosis—If the ostium of a suppurating sinus be occluded pus is secreted under pressure and the local symptoms are severe, whereas if the secretion can escape freely there may be no symptoms except discharge The former class of case has been called "closed" and the latter "open" empyema The difference between the two is, however, only relative, and many cases are alternating the severe symptoms being relieved by periodical discharge As the pressure of pus in the cavity depends on the rapidity of its secretion and the degree of occlusion of the ostium by inflammatory swelling, it follows that the closed and open cases correspond generally to acute and chronic suppuration, acute suppuration is usually fairly obvious, but some chronic cases with scanty discharge are only to be detected after very careful examination and may be for long the undiscovered cause of post-nasal catarrh, pharyngitis or chronic toxæmia In all doubtful cases a radiograph should be taken

The symptoms are pain tenderness and discharge, together with the secondary effects of the suppuration Pain is often severe in acute cases and in chronic suppuration there may be a heavy feeling over the face Frontal pain of an intermittent character relieved by a sudden gush of discharge from the nose is highly characteristic of sinus disease, as also is a peculiar periodicity, for it tends to begin regularly at the same time every morning and to get better during the afternoon Tenderness can usually be elicited in frontal empyema by percussion over the anterior wall, and especially by pressing upwards against the floor of the cavity, in antral disease tenderness over the canine fossa is uncommon Discharge into the nose is the most important, and often the only, symptom A localised stream of pus which reappears after removal is, in the absence of a foreign body or malignant disease, conclusive evidence of suppuration in an accessory sinus Further assistance is afforded by transillumination and skiagraphy, though transillumination is a somewhat unreliable test. A good radiograph will usually demonstrate clearly the extent of the disease, and puncture of the antrum with trocar and cannula should be carried out in doubtful cases Fœtor, both subjective and objective, is not common, and when present it must arouse the suspicion that the primary cause is dental

Complications.—These include pharyngitis, laryngitis, bronchitis and otitis media; the swallowed pus causes various forms of gastric and intestinal disorders. Acute septicæmia and pyæmia are rare, but symptoms of chronic poisoning are common, and include anæmia, arthritis, fibrositis and even mental aberrations. A very important series of complications results from extension of the inflammation to surrounding parts—orbital abscess or cellulitis, osteomyelitis of the frontal bone, cerebral abscess, meningitis, thrombosis of the cavernous sinus.

Treatment—This in the most acute stages entails complete rest in bed. Inhalations are of little value and give rise to much unnecessary exhaustion. It is useful to promote shrinkage of mucosa in the middle meatus by prescribing ephedrine, 0.5 per cent. in normal saline, dropped into the nose when the head is bent backwards, or introduced by means of an atomiser. Analgesics and hypnotics should not be withheld. Antibiotics should be prescribed for severely ill patients in the acute stage, especially if the frontal sinus is known to be involved. Penicillin is usually effective though there is some evidence to show that chloramphenicol is even better. In recent cases of antral suppuration the cavity should be punctured and washed out with saline, a procedure which in most cases must be repeated every 3 or 4 days until the washings are returned clear.

Acute frontal sinusitis is scarcely ever seen in the absence of an infected aotrum on the same side. If the antrum is successfully treated the frontal sinus will almost always recover spontaneously, though it may be necessary when the more acute stage has passed to rectify anatomical or pathological conditions which interfere with the patency of the fronto nasal duct. Thus, the anterior end of a middle turbinate may have to be infracted or even removed, or the septum may have to be straightened. Cases which fail to recover under such treatment have entered upon the chronic stage and sooner or later will require an external operation.

DISEASES OF THE NASO-PHARYNX

ADENOIDS

Ætiology.—By this term is implied chronic enlargement of the lymphoid tissue in the naso-pharynx. This is normally present in childhood and disappears by the age of 20 or thereabouts. The precise stage at which enlargement becomes pathological can only be determined by the symptoms, these usually become manifest between the ages of 3 and 8, but occasionally show themselves at or soon after birth. The incidence of adenoids is universal, but it is in damp temperate climates that the child population is most affected. Lymphoid tissue may hypertrophy during an attack of measles or scarlet fever, and a series of severe colds will lead to permanent hypertrophy.

Pathology—The adenoid, as it should really be called, or enlarged pharyngeal tonsil, is a mass of lymphoid tissue of definite anatomical shape, it is thickest above and tapers away below, and presents a series of ridges which radiate from below upwards and slightly outwards. In older patients the mass is firmer and more fibrous, and the ridges are often adherent in places, leaving deep clefts and furrows in which secretion can collect and decompose.

Symptoms—The symptoms of adenoids are many and various, and include those due to nasal obstruction, those caused by infection and by the extension of inflammation, and reflex processes attributable to irritation and lowered vitality. In infants nasal obstruction interferes with sucking and a serious degree of malnutrition will result unless the baby be carefully spoon fed. Older children snore at night, breathe heavily in the day, and either bolt their food or eat very slowly owing to the

necessity of breathing through the mouth. Lack of oxygen induces restless sleep, patients wake unrefreshed and develop an inability to concentrate. Persistent nasal obstruction during the period of growth mechanically produces permanent deformities of the jaws and face which narrow the nasal passages, prevent the mouth from closing naturally and thus perpetuate mouth-breathing. When the mouth is habitually held open the alar nasi are pulled downwards with the cheeks, become narrow and slit like and fall in like valves with each inspiration, this "alar collapse" is an important cause of obstruction in neglected cases of adenoids. The palate is narrow and highly arched, the dental arch is narrow and V shaped, so that the upper incisors are crowded and prominent, look outwards rather than forwards and are not covered by the short upper lip, the lower jaw retains its infantile obtuse angle, and the lower incisors lie behind the upper, the chin is receding and, in the worst cases, when the molar teeth come into contact on biting, the incisors cannot meet. Only a proportion of cases of adenoids show these deformities and there is, indeed, considerable uncertainty as to the importance of adenoids in their etiology, undue softness of the bones such as occurs in rickets, is doubtless an additional factor, and also in the causation of the malformations of the chest which result from obstruction to the entry of air. The long narrow unexpanded chest with acute costal angle and prominent scapulae is the commonest deformity. Harrison's sulcus, a transverse depression corresponding to the attachment of the diaphragm, pigeon-breast, a prominent sternum with depressed costal cartilages, and funnel breast, a sharp depression at the lower end of the sternum are also encountered.

Various infective processes result from the spread of inflammation and if the naso-pharynx be large are not necessarily associated with nasal obstruction. The common catarrhal and suppurative affections of the ear in children are, in an overwhelming majority of cases the result of adenoids. Blepharitis and phlyctenular conjunctivitis are also associated with adenoid vegetations. Feverish attacks often with tender enlargement of the cervical glands, are caused by infection of the adenoids and tonsils and tuberculous disease of the glands is usually due to passage of the bacilli through these portals. In such cases the tonsils and adenoids may remain unaffected or may themselves show tubercles when examined under the microscope. Chronic or recurrent bronchitis frequently results from the infection spreading to the lower air passages. The mucus secreted by the adenoids is swallowed in large quantities, and produces derangements of stomach and intestines with failure of growth and general health. Finally, mouth breathing predisposes to dental caries. The irritation of these vegetations and their effect on respiration and the general health account for numerous reflex and nervous disturbances, such as cough, laryngitis with spasm and laryngismus stridulus, more remote conditions, stammering, night terrors and nocturnal enuresis are sometimes ascribed to adenoids, but are by no means always cured by their removal.

Diagnosis.—Tractable children usually permit the use of a small post nasal mirror through which a satisfactory view of the naso-pharynx can be obtained. An irregular convex mass can be seen, sometimes so large that other landmarks are obscured. In nervous children if the symptoms point strongly to adenoids, it is wiser to give an anæsthetic for examination, being prepared to remove the vegetations if present. Digital examination of the naso-pharynx without an anæsthetic is cruel and should not be undertaken. Infection of one or both antra is not uncommon in small children, such infection may coexist with hypertrophy of adenoids and tonsils. Disappointment after operative removal of tonsils and adenoids can often be explained by the fact that antral infection has not been discovered. Some rhinologists go so far as to have all children radiographed before operation, if infection is confirmed antral lavage can be carried out under the same anæsthetic. In the mongolian type of idiocy the tongue is large and the mouth persistently open, and in microcephaly the extremely undeveloped naso-pharynx causes nasal obstruction, cases of both these

types of maldevelopment are often brought to the doctor in the hope that removal of their adenoids will cure their "backwardness", and care should be taken not to fall into the error of performing a useless operation. On the other hand, adenoids can be present and produce serious secondary effects without causing nasal obstruction or any appearance of the typical "adenoid facies".

Treatment.—The normal naso-pharyngeal tonsil becomes swollen during coryza, and such temporary swelling should not be diagnosed as "adenoids".

When the enlargement frequently recurs or has gone on to chronic hypertrophy, operative removal is the only treatment, and this is especially called for when any aural symptoms supervene, or when cervical adenitis is present. If the *alæ nasi* are collapsing, or the chest narrow, breathing exercises are important and should be started forthwith.

DISEASES OF THE LARYNX

ACUTE LARYNGITIS

Ætiology.—This affection most often occurs during the course of a cold, the inflammation spreading downwards from the nose and naso-pharynx. Over-use of the voice will precipitate an attack, especially if voice production is faulty. It arises in the course of acute infectious fevers such as influenza, measles or scarlatina. Predisposing causes are nasal obstruction, infection of sinuses, tonsils or teeth and sedentary occupations in ill-ventilated overheated rooms. Acute laryngitis of a non-tuberculous nature is not uncommon in patients with pulmonary tuberculosis.

Symptoms.—The symptoms consist of hoarseness, local discomfort varying from dryness or tickling to a burning sensation or actual pain and irritating cough. There is little expectoration, unless the trachea and bronchi are involved. At the onset there may be slight feverishness and malaise. The degree of hoarseness is by no means proportionate to the objective appearances; the voice may be quite good in cases of decided hyperæmia, and may be completely lost when little abnormal is to be seen. A muscular man may retain a strong voice with a degree of inflammation which would render a weakly woman almost apbonic—indeed some women lose the voice with every slight cold, so that it becomes difficult to differentiate between laryngeal catarrh and "functional aphonia". On the other hand, in some voice-users redness of the cords appears to be the normal condition and causes no interference with function. This variable effect on the voice is to be observed in all forms of laryngeal disease. In children, acute laryngitis is a serious affection. They show a far greater tendency to œdema and to spasm and, as the glottis is not only absolutely but relatively smaller than in adults, dangerous dyspnoea may ensue with great rapidity. The larynx is reddened, and this is most obvious on the parts usually pale—the epiglottis and vocal cords, the vessels on the former being unduly prominent. The cords may be red or salmon pink, or may merely have lost their bright pearly lustre. A small amount of mucous secretion is generally present, but no large accumulations or strings of mucus, such as are seen in chronic laryngitis.

Treatment.—The patient should be confined to a warm (65° F.), well-ventilated room, preferably in bed, and must not attempt to use the voice. Steam inhalations are of value and may be used from an inhaler or from a jug round the mouth of which a towel has been wrapped in the shape of a cone. The water should be at a temperature of 130° to 140° F., and fl. dr. 1 or 2 of tinct. benzoin co. (Friars' balsam) should be added to the pint. This simple prescription cannot be improved upon though it is sometimes worthwhile incorporating menthol gr. 10. Inhalations should only be prescribed when the patient is confined to his room. At a later stage instruction

may be given in the use of an atomiser of the de Vilbriss pattern charged with protargol 10 per cent. Internally, expectorants are indicated; tinctura specacuanha, min. 10, or visum antimoniale, min. 5, potassium iodide, gr. 2 or 3, ammonium carbonate, gr. 4, every 4 or 6 hours. If cough is severe it should be restrained by means of a tincture containing codeine phosphate gr. $\frac{1}{2}$ or liquor morphinae, min. 2 to 4 to each drachm.

CEDEMATOUS LARYNGITIS

Synonym.—Edema of the Larynx.

Ætiology.—Edema of the larynx is not a disease but a pathological condition due to a variety of causes. Non-inflammatory edema may be mentioned here for the sake of completeness; it occurs, though rarely, as part of the general anasarca of renal and cardiac disease. Angio-neurotic edema sometimes occurs in the larynx, in which event it produces rapid and sometimes fatal dyspnoea (see p. 1255). The swelling which occasionally results from administration of potassium iodide in susceptible subjects may be placed in the same category.

Inflammatory edema seldom results in adults from a simple catarrh, but it may do so in children; it more often occurs as part of an acute septic infection of the pharynx, trachea and bronchi, "acute fulminating laryngo-tracheo-bronchitis" (q.v.). Edema may follow various forms of trauma, the drinking of corrosive poisons, inhalation of irritating vapours such as the poison gases of warfare, the lodgment of foreign bodies or rough or unduly prolonged bronchoscopy. Scalding, from attempts to drink from a kettle-spout, is a common cause among children. In other cases it is a sequela of typhoid fever, pneumonia, scarlet fever or small-pox, and is a local complication of syphilitic, tuberculous, cancerous or traumatic ulceration.

Symptoms.—If part of a septic pharyngo-laryngitis, the general symptoms are severe. The chief local symptom is dyspnoea with inspiratory stridor and the associated symptoms of asphyxiation; there is hoarseness or aphonia, local discomfort and tenderness and sometimes dysphagia. The aryteno-epiglottidean folds are enormously swollen, appearing as pale or purple translucent flask-shaped masses; if the epiglottis be oedematous it forms a sausage-shaped swelling of the same appearance. The mucosa of the vocal cords is too adherent to permit much swelling, and "edema of the glottis" is therefore a misnomer. The subglottic region is lax and may become swollen; indeed, the edema may be confined to this region and then appears as a red swelling below each vocal cord. In children edema may be inferred from the steadily increasing dyspnoea without the rapid increase and decrease typical of spasmodic laryngitis.

Treatment.—Patients should be nursed in a semi-sitting position. In slight cases, the swelling may be reduced by sucking ice and by the application of an ice-bag to the neck; the latter is inadmissible in young children. A spray of adrenaline, 1 in 1000, may be used. Hypodermic injections of pilocarpine, gr. $\frac{1}{4}$, are recommended, and for the edema produced by iodides, large doses of bicarbonate of soda. When edema is the result of an acute streptococcal infection, full doses of sulphonamides and penicillin should be given without delay. Scarification of the oedematous tissues with a curved bistoury, which was accepted practice in the past, is now not recommended because of the disturbance it causes to patients, the danger of blood entering the trachea and the chances of giving rise to secondary infection. Tracheotomy should be performed before respiratory embarrassment is too great; intubation is not recommended. Angio-neurotic edema should be treated by a spray of adrenaline, but as this condition is often allergic in origin it is logical to prescribe full doses of one of the "anti-histamine" drugs such as promethazine or phenindamine. Intravenous calcium gluconate is excellent treatment. Very rarely tracheotomy may be necessary.

MEMBRANOUS LARYNGITIS

The formation of false membrane in the larynx is nearly always part of an attack of diphtheria which is discussed elsewhere, but the term "membranous laryngitis" implies formation of membrane of non-diphtheritic origin. Apart from traumatic cases, due to irritating chemicals and scalds, inflammation of the larynx accompanied by membrane may be caused by streptococcal infection. The affection occurs especially in children between the ages of 2 and 8 years (see Acute Laryngo-Tracheo-Bronchitis, p. 946). The diagnosis from diphtheria is only possible by bacteriological examination, and pending the report the case should be treated with antitoxin. It may be noted that the pharynx is nearly always involved in diphtheria, whereas in membranous laryngitis the disease is often primary in the larynx. The prognosis is grave and worse than that of diphtheria since the introduction of antitoxin.

ACUTE LARYNGEAL CONDITIONS AFFECTING CHILDREN

In the past it has been customary to describe a group of acute laryngeal conditions occurring in early childhood, all of which are associated with dyspnoea. A great deal of unnecessary confusion has arisen because there has been (and still is) some uncertainty as to the mechanism of such conditions. An unfortunate nomenclature has been evolved which is muddling and unhelpful.

An attempt will be made to clarify the situation by confining description to acute laryngitis in children, acute laryngo-tracheo-bronchitis, congenital laryngeal stridor and laryngismus stridulus.

For years the expression croup has been used so universally that many have wrongly supposed that the term denoted a definite disease. The word dates from a period when diagnosis of diseases of the throat was far from exact and the meaning was obstructive dyspnoea. The adjective "croupy" may still be used to describe noisy inspiratory stridor, itself a symptom of diverse laryngeal affections.

ACUTE LARYNGITIS IN CHILDREN

In young children the larynx is small whilst the cartilages are soft and yielding. The mucosa is rather loosely connected to subjacent tissues so that effusion can take place more readily. It seems that the controlling nervous mechanism is somewhat unstable and that glottic spasm is more easily evoked. For these reasons laryngitis in children is always a serious condition, and alarming symptoms, especially dyspnoea and cyanosis, may develop with extreme rapidity. A child, save for a slight cough, may seem well during the day and then at night may suddenly develop laryngeal spasm and become seriously ill. Acute laryngitis with spasm is a better name than the old-established "laryngitis stridulosa", a term which, though accurate enough, has served to confuse generations of medical students.

Treatment.—The time-honoured treatment has been "an emetic and a purge". Emetics are certainly helpful in some cases and tincture ipecacuanhae, min. 60, may assist in the removal of obstructing secretions. An aperient may be given, remembering that there is no specific virtue in calomel. It is well to put up a steam kettle, and there are occasions when oxygen will be required. Antibiotics will not directly relieve laryngeal spasm but may be indicated to control the primary infection. Very rarely indeed is tracheotomy required. When the acute attack has passed the child should be examined with a view to eliminating unhealthy adenoids or tonsils.

ACUTE LARYNGO-TRACHEO-BRONCHITIS

Ætiology.—This severe disease usually occurs in children under 3 years of age and is rarely seen after the age of 6. Weakly children are most often affected and the mortality even now is about 15 per cent. The responsible organisms may be streptococci, staphylococci, pneumococci or influenza bacilli. There is redness and swelling of the arytenoid region and gross subglottic swelling which spreads down into trachea and bronchi. An exudate is poured out into the tracheo-bronchial tree and quickly becomes thick and tenacious; its expectoration is often beyond the strength of the patient. Pneumonia and atelectasis from plug formation form a prominent part of the clinical picture.

Symptoms.—In most cases the disease develops comparatively slowly; only occasionally is an infant rapidly prostrated. The following graphic description is quoted from F. C. Emery. "As the disease progresses these patients become dehydrated, prostrated and finally present a picture of complete collapse. The cyanosis disappears, leaving an ashen pale skin and anoxic coma, with all the remaining energy being spent on breathing. Retraction may be so great that the sternum and thoracic spine seem to meet with each gasping inspiration."

Treatment.—Humidification of inspired air is important and a steam kettle can be used with advantage. Almost all cases must be at some time nursed in an oxygen tent; a mixture of helium and oxygen has been recommended by Jackson. Sleep is a grave problem as drugs given to ensure sufficient rest damp down the cough reflex. On the other hand, continual coughing may so sap the patient's physical strength that some opiate must be given. In theory causative organisms should be isolated and tested for sensitivity to the various antibiotics and sulphonamides, but time should not be wasted whilst waiting for the bacteriologist's report. Penicillin is generally useful, but evidence is mounting which suggests that chloramphenicol is substantially more effective. Every effort must be made to keep up the fluid intake.

Bronchoscopy often becomes an urgent necessity, for this may be the only practical method of ridding a patient of tenacious secretions and pseudo-membranous sloughs. Sometimes even this procedure is inadequate and an emergency tracheotomy is indicated. It must be remembered that obstruction to respiratory exchange may be as great below the tracheotomy as above it, but an opening in the trachea facilitates lavage and suction.

CONGENITAL LARYNGEAL STRIDOR

In this condition there is an exaggeration of the infantile shape of the upper aperture of the larynx; the epiglottis is sharply folded laterally, the ary-epiglottic folds are almost in contact, and the opening is thus reduced to a narrow vertical slit. As these parts are very flaccid in infancy, they become sucked together during inspiration and, by their vibration, produce the characteristic stridor. This stridor is noticed very soon after birth, it is inspiratory, of a peculiar purring or even musical character, and is most marked during active breathing and crying. The voice is unaffected, and there is remarkably little sign of dyspnoea or distress. These characteristics distinguish the condition from other forms of obstruction found in infants, such as laryngeal webs or papillomata, or "thymic asthma". Symptoms tend to disappear during the second year of life, but the prognosis must be guarded in early infancy, for an attack of bronchitis is more than ordinarily dangerous and kills a proportion of these patients.

LARYNGISMUS STRIDULUS

Ætiology.—This is a condition, clinically similar to glottic spasm, occurring in children. It is far commoner than the spasm of adults, and it has been suggested that the asphyxial attacks of laryngismus are caused by collapse of the soft and yielding cartilaginous framework of the larynx, and not solely by spasm of the muscles. It is commonest between the ages of 6 months and 2 years, but may persist later; it occurs in ill-nourished unhealthy children, often in association with rickets, and practically always in association with adenoids.

Symptoms.—The onset is sudden and attacks usually occur at night. The child wakes gasping for breath, and a series of short noisy inspirations is followed by complete cessation of breathing; a long crowing inspiration terminates the attack. There are retraction of the lower ribs and epigastrium, cyanosis and great terror and distress and, in severe cases, carpo-pedal contractions, convulsions and evacuation of urine and faeces. When the attack is over the child is perfectly normal and there is no hoarseness. Slighter and less typical attacks often occur.

Diagnosis.—This is easy if the symptoms are carefully noted; the sudden attack of dyspnoea, with complete absence of symptoms in the intervals, is quite distinctive.

Prognosis.—The prognosis is somewhat grave in severe cases; an infant rarely dies in an attack, but is often worn out and eventually succumbs to collapse of the lungs.

Treatment.—During the attacks the face and chest may be freely sponged with cold water, and the inhalation of amyl nitrite from a capsule broken in a handkerchief may be tried. The child should be supported sitting up, and the quickest relief can usually be obtained by drawing the tongue forward with a finger passed into the mouth to its base, a manoeuvre easily performed by the mother or nurse. The attacks are so short and sharp that there is no time for the hot bath or administration of bromides frequently recommended.

Prevention involves the control of rickets with vitamin D, fresh air, wholesome food and correction of digestive disturbances. Attention should be given to eliminating infection in the nose, and drops of protargol, 2½ per cent., may be instilled when the child is in the head-down position. It is particularly important to remove adenoids even if they are only moderately enlarged.

CHRONIC LARYNGITIS

Ætiology.—The causation is similar to that of acute catarrhal laryngitis; indeed, chronic laryngitis is often the result of recurrent acute attacks. The principal factors which predispose to chronicity are nasal obstructions and discharges, dental infections and chronic tonsillar sepsis, dusty occupations and lack of fresh air, over-use of the voice and faulty voice production, and the abuse of alcohol or tobacco; consumptives are particularly liable to non-specific catarrhal laryngitis. Almost any use of general ill health may be included among the predisposing causes.

Symptoms.—The only constant symptom is impairment of the voice, which is hoarse, easily tired or, rarely, almost completely lost. It is sometimes weakest when uttered in the evening, but is often at its worst on rising in the morning or after a rest. There is frequently a sensation of aching, dryness, tickling or of a lump in the throat, and there is usually some cough, but little expectoration unless the trachea and bronchi are involved.

The objective appearances vary with the severity of the affection. The larynx is generally of a deeper red than usual, and the vocal cords have lost their normal early lustre and are pink; they are usually somewhat thickened at the edges, and enlarged vessels may be visible on their surface; the vocal processes are often prominent and may be reddened or show up white against the hyperæmic cord. Strings

of sticky secretion may stretch between the cords, or a little globule of mucus may form on the centre of the cord during phonation, adduction is frequently imperfect. When the epiglottis is reddened, its yellow edge stands out clearly and enlarged vessels are visible, the ventricular bands are often swollen so as to hide the outer part of the cords. The mucous membrane in the inter-arytenoid space is seen to be thrown into folds on adduction of the cords, and may form a mass large enough to prevent their complete approximation. The general picture is one of symmetry, a useful point in diagnosis when tuberculous laryngitis is in question.

A patient suffering from atrophic rhinitis may develop an unusual form of chronic laryngitis known as *laryngitis sicca*, in which small brown scabs adhere to the cord and posterior commissure, but occasionally the disease itself spreads to the larynx which is covered by large greenish or brownish black fetid crusts, more rarely still the crusts extend into the trachea and cause severe dyspnoea.

Pachydermia laryngis is an uncommon variety of chronic laryngitis, occurring principally in middle aged men. It is frequently ascribed to alcoholism though perhaps on insufficient grounds and the diagnosis between pachydermia and tuberculosis or syphilis is often a matter of difficulty. The characteristic epithelial thickenings are probably of the nature of corns, resulting from frequent cough and continuous irritation. There is hoarseness of a rough raucous character, but no particular discomfort. The epithelial thickening is pink or whitish and occupies the posterior region of the glottis from the vocal processes backwards to the posterior commissure. A circumscribed swelling appears on each vocal process, with a small cup or depression at the apex—the approximation of the cords is better than would be expected because the prominence on one vocal process fits into the depression at the other. The epithelium of the inter-arytenoid space is thrown into ridges, which fill up the angle between the arytenoid and the posterior commissure, but leave a depression in the middle line. These firm opaque, symmetrical swellings, without ulceration, are distinguishable from the soft irregular granulations of a tuberculous lesion.

Treatment.—The detection and correction of the ætiological factors are the most important part of treatment. Any constitutional disturbance, such as anaemia, rheumatism, gout or dyspepsia, should receive attention. Over indulgence in tobacco or alcohol, lack of ventilation and exposure to dust must be considered, and with teachers the blackboard chalk is a common source of irritation.

Incorrect voice production is a factor of great importance and a good speech therapist can often provide substantial help.

Almost always some infection is discovered in nose, sinuses, tonsils or teeth. Elimination of such infection is the most important step in treatment.

Locally, treatment must begin with rest of the voice, which should be absolute in the case of professional voice users. Where there is much secretion a saline lotion may be used in a spray—sodium bicarbonate, borax, sodium chloride gr 10 of each, glycerin, 60 min, water to 1 oz. Oily solutions are usually preferred such as menthol gr 5 camphor gr 2, chlorbutol gr 5, or oil of eucalyptus in similar proportions, to 1 oz of liquid paraffin. The direct application of pigments is not often called for, and is to be recommended only when pachydermatous changes are present. Dundas Grant advised an alcoholic solution of salicylic acid beginning with 1 per cent. and increasing to 6 or 8 per cent.

Internally, small doses of potassium iodide, gr 2 or 3 three times a day over long periods, is of value.

TUBERCULOUS LARYNGITIS

Ætiology.—In all cases the disease is secondary to pulmonary tuberculosis of which it is an important complication. It is probably caused by infection from the

sputum, is commoner in men than in women, and is most frequent between the ages of 20 and 40. St Clair Thomson found that the difference in sex-incidence is occupational, and that women working in office and factory are as susceptible as men.

Symptoms.—The disease attacks, in order of frequency, the vocal cords, arytenoid region, inter-arytenoid space, ventricular bands and epiglottis; in general the glottis is invaded before its upper aperture. The typical infiltration is finely nodular, pallid and soft in appearance; ulcers are shallow, with a smooth speckly base and pale ill-defined margin. On the vocal cord the disease chiefly attacks the posterior half and especially the vocal process, where ulceration readily reaches the underlying cartilage and may produce a deep triangular excavation. Thickening in the inter-arytenoid region is common; infiltration of the ary-epiglottic folds results in typical pale semi-translucent flask-shaped swellings, while the epiglottis appears as a firmer red sausage-shaped mass.

The voice is weak and has not the raucous quality associated with syphilis. Sometimes voice production is actually painful. Cough and expectoration are mostly due to the pulmonary disease and not in any considerable degree to the larynx. Pain on swallowing is common and often very intense; there may also be actual obstruction to deglutition and, in a late stage, entry of food into the larynx. Dyspnoea is rare.

Diagnosis.—Although signs of pulmonary tuberculosis are helpful in diagnosis, it is obvious that any kind of laryngeal disease may occur in a consumptive patient.

From simple laryngitis.—In the earliest stage of invasion tuberculous laryngitis may exactly resemble catarrhal laryngitis, but redness of one cord only is certainly not due to catarrh, and the latter quickly improves under treatment. Inter-arytenoid infiltration resembles pachydermia, but the latter is opaquely white, firm and symmetrical.

From lupus, typical tuberculosis differs completely. The former is painless, affects first the epiglottis and upper aperture, is never accompanied by oedema, and tends to cicatrization. But there is a chronic "lupoid" form of tuberculous laryngitis which attacks the epiglottis and is very similar to lupus.

From syphilis.—The tuberculous ulcer has an ill-defined margin without surrounding hyperæmia; the base has a yellow speckled appearance, and on healing there is little scarring or contraction. The superficial syphilitic ulcer has a well-defined hyperæmic margin, with a smooth, flat base; the deep ulcer is "crateriform", with thickened punched-out edge, and, on healing, leaves a dense scar and marked deformity. In general, syphilitic lesions attack the anterior half of the larynx, tuberculous the posterior; the former look firm and dense, the latter, soft, translucent and ill-defined.

From neoplasms.—Only the rare tuberculomata resemble innocent tumours. Occasionally tuberculosis attacks one vocal cord in an elderly patient, and may then easily be mistaken for epithelioma, especially when, as often happens in such cases, the pulmonary signs are inconclusive and tubercle bacilli absent from the sputum.

Prognosis.—This has greatly improved in recent years due to advances in the chemotherapy of tuberculosis.

Treatment.—Tuberculous laryngitis is but a complication of pulmonary tuberculosis, and by far the most important part of the treatment is that of the general infection. Complete vocal rest has in the past been the mainstay of treatment; this is a severe and depressing measure and it is now not always necessary to enforce complete silence. Streptomycin, combined with isoniazid or sodium aminosalicylate (P.A.S.) not only promotes healing of laryngeal lesions but within a very short time abolishes pain and dysphagia. It should now never be necessary to use a galvanocautery or to insufflate analgesic powders, let alone to inject alcohol around the internal laryngeal nerve. In these days one no longer sees the desperate case of tuberculous

laryngitis in which the airway becomes obstructed and tracheotomy is called for. There have, however, been rare cases of cicatricial stenosis following "successful" chemotherapy.

PARALYSIS

Paralysis of a vocal cord occurs in association with various diseases of the thorax and of the nervous system. The early form, unilateral abductor paralysis, causes no symptoms, and can only be recognised by laryngoscopic examination.

The original function of the laryngeal muscles is that of a sphincter to prevent the entrance of fluid into the lungs, and this sphincter, or adductor, is the only muscle present in the larynx of primitive air-breathing animals; the abductors are a later addition. In progressive lesions involving the nerve pathways the abductor muscles are first affected whilst the adductors continue to function for a variable time. The function of phonation, much more recently acquired, is associated with adduction and is under direct control of the will. Functional disturbances, therefore, always cause adductor paralysis, while organic lesions first affect the movement of abduction.

ORGANIC PARALYSIS

The crico-thyroid muscle is supplied by the superior laryngeal nerve, and when this is injured the affected cord remains slack on phonation, but owing to the short course of the nerve isolated paralysis of this muscle is extremely rare; it results from surgical or suicidal wounds, and may occur after diphtheria. In lesions of the vagus above the origin of this branch the signs of this paralysis are obscured by that of the other muscles of the cord. The recurrent laryngeal nerves supply all the other muscles. In any progressive lesion of the nerve pathway the muscles become paralysed in a definite order; the abductors are first affected, then the internal tensors or thyro-arytenoidei and finally the adductors. This is known as Semon's Law.

There is but one muscle on each side which acts as an abductor of the vocal cord, namely, the crico-arytenoideus posticus (often, for convenience, alluded to as the posticus muscle). This muscle not only moves the vocal cord away from the midline during respiration, but its most posterior fibres brace back the arytenoid cartilage and stretch the aryepiglottic fold. The cartilage of Wrisberg is incorporated in the fold and helps keep it taut in an upright position. Thus it is that in "posticus" paralysis the aryepiglottic fold droops inwards and the cartilage of Wrisberg tilts forwards and inwards with it. Yet another thing happens, the arytenoid cartilage is free to slide and tilt forwards so that the cord appears shortened and tends to lie at a slightly lower level. This forward tilting and apparent prominence of Wrisberg's cartilage is of help in diagnosis.

ABDUCTOR PARALYSIS

The affected cord lies immobile in the midline, being held there by the unopposed action of adductor muscles (crico-arytenoideus lateralis and inter-arytenoideus). On phonation the unaffected cord swings over to meet its immobile fellow so that the voice is unaltered. It is not quite true to say that during phonation the larynx appears normal, for on the sound side Wrisberg's cartilage seems to move forward in front of its fellow. The glottic aperture is reduced but dyspnoea is only noticed on exertion.

Bilateral abductor paralysis is a serious condition, particularly if the onset is sudden, as both cords lie together in the middle line, leaving a mere chink. Inspiratory

embarrassment is extreme, but the conical shape of the subglottic region allows expired air to blow the glottis open. The voice is quite good, though the patient must constantly pause in a vain attempt to fill the lungs. Were it not for forward displacement of the arytenoid cartilages referred to above, thus allowing a cink, patients would asphyxiate.

COMPLETE PARALYSIS

When only the recurrent laryngeal nerve is involved the affected cord assumes a "paramedian" position for the crico-thyroid muscle, an external tensor and weak adductor, is still acting. The cadaveric or intermediate position can only be assumed when this muscle also is paralysed, as in a lesion of the main vagus trunk above the superior laryngeal nerve from which it derives its innervation. The true cadaveric or intermediate position is half-way between abduction and adduction, whereas the paramedian position is somewhat nearer the midline. Few observers could distinguish such a small positional difference were it not for the fact that when the crico-thyroid muscle is acting there is still some cord tension, and when paralysed tension is absent, so that the cord presents a wavy appearance. The affected cord during respiration appears shorter and lies at a slightly lower level, and the cartilage of Wrisberg seems unduly prominent. The reasons have already been given when discussing the effects of posticus paralysis.

In a unilateral case, whether the lesion is true recurrent nerve palsy or high vagus palsy, there is at first inefficient closure of the glottis and a feeble husky voice results; air waste on phonation is characteristic. As time goes on the voice may improve because the unaffected cord compensates and swings right across the midline on phonation. At first there may be some overflow of water or food into the trachea but this also improves as time goes on.

When complete paralysis is bilateral there can be no hope of efficient glottic closure. The voice is feeble and "breathy," whilst spilling over into the trachea is a constant source of worry. Breathlessness is usually only evident on exertion. Bilateral complete paralysis is fortunately very rare.

Diagnosis.—The diagnosis is almost entirely a matter of accurate inspection. Obliquity of the laryngoscopic image, due to faulty position of the mirror, may cause confusion. In nervous subjects the cords are sometimes adducted on inspiration, but they will abduct naturally during the involuntary inspiration which follows a prolonged phonation. The only condition which really imitates paralysis is the fixation of the arytenoid cartilage which results from disease in or around the joint; its complete immobility with the presence of swelling or scarring often aids the diagnosis, but in old-standing cases of paralysis secondary fixation frequently occurs. In cases of arytenoid fixation there is no "dropping forward" of the cartilage of Wrisberg.

Ætiology.—The movements of the cords are represented bilaterally in the cortex cerebri, and stimulation of either centre produces movement (adduction) of both cords, from which it follows that no unilateral lesion above the bulbar nuclei can paralyse the larynx, and clinically we find that it is never affected in cases of hemiplegia. The bulbar centres lie in the floor of the fourth ventricle, and here a lesion of one centre causes paralysis of the cord on the same side which, in a gradually progressive lesion, affects first the abductor muscle. Thence the nerve fibres pass in the roots of the bulbar-accessory to the vagus and recurrent laryngeal nerve; the cause of the paralysis may, therefore, be situated (1) in the medulla, (2) at the base of the skull, (3) in the vagus or (4) in the recurrent laryngeal nerve.

Paralyses of bulbar origin are often, but by no means always, bilateral. In lesions here and at the base of the skull neighbouring nerves are liable to be involved; thus, paralysis of a cord and of the palate on the same side may coexist (syndrome of Avellis), or paralysis of cord, palate, trapezius and sternomastoid from involvement of the

spinal accessory roots, or persistent tachycardia due to damage of the cardio-inhibitory centre or nerves. *Tabes dorsalis* is the most frequent cause of paralysis of central origin; it may effect one or both cords and may be associated with anæsthesia, paræsthesia or the spasmodic attacks called "laryngeal crises". In general paralysis of the insane laryngeal palsy is not uncommon. It is the rule in bulbar paralysis, and is usually bilateral, but appears late in the disease. Syphilitic nuclear disease, pachymeningitis and gummata at the base of the brain are now rare causes, and here the ocular muscles, especially the external rectus, are often attacked.

Peripheral causes usually act by compression of the recurrent nerve, the most frequent being aneurysm, enlarged glands, tuberculous or malignant, and cancer of the œsophagus. Other causes are thyroid tumours, usually but not necessarily malignant, mediastinal tumours, cancer of the lung, pleurisy and pulmonary tuberculosis in which the nerve, usually the right, may be involved in a lesion at the apex of the lung or by tuberculous bronchial or tracheal glands. Neuritis is a cause of laryngeal paralysis; it may be produced by the toxins of diphtheria, or by organic poisons, especially lead, and more rarely arsenic and alcohol. Finally, the condition is not uncommonly the result of trauma, more especially surgical operations on the thyroid gland and lung.

Prognosis.—Paralysis of one cord is not in itself dangerous to life; but when the cause is undiscovered the prognosis must be guarded, for this paralysis may be for a long time the only sign of serious disease; on the other hand, the recurrent laryngeal nerve may be involved in some non-progressive lesion, such as a fibrotic bronchial gland, and such cases have been under observation for 20 or 30 years without change.

Treatment.—This depends on the cause. In most cases it is but a symptom of disease elsewhere and does not call for special treatment. In cases due to neuritis, atropine and the local application of the faradic current by means of an intra-laryngeal electrode are indicated. Tracheotomy is advisable in bilateral abductor paralysis. A specially designed tube in which a valve is incorporated is used; this valve allows air to enter freely on inspiration but closes during expiration so that the voice remains unaffected. Operations devised to fix one arytenoid cartilage and vocal cord in a more lateral position sometimes give satisfactory results.

All patients suffering from laryngeal paralysis must be forbidden to swim.

FUNCTIONAL PARALYSIS (FUNCTIONAL APHONIA)

Ætiology.—Functional aphonia is a common manifestation of hysteria and occurs chiefly in young women. Many cases were encountered amongst men during the War of 1914–1918 and the War of 1939–1945, men whose terrifying experiences had driven them into a state of "battle exhaustion". Anæmia, debility and local inflammatory conditions may predispose to an attack of aphonia, but it seems clear that the condition would not materialise without some hysterical background. It is true that some women are rendered aphonic by acute laryngitis of moderate severity, but it is not the inflammatory process which prohibits cord approximation.

Symptoms.—Paralysis of the adductors presents a totally different clinical picture from organic paralysis. It is always bilateral; the larynx appears normal while at rest, but, on attempts at phonation, it is seen that the cords do not adduct into the position necessary for the production of the voice. Occasionally the internal tensors alone are working inefficiently, an elliptical chink is left between the cords anteriorly. If the crico-arytenoid laterales are parietic, the entire glottis remains open to a variable extent, and, very rarely, the arytenoid is affected alone, when a triangular aperture is left behind the vocal processes. The paralysis is hardly ever complete; indeed a considerable amount of movement is usually seen, though insufficient to produce phonation. In purely hysterical cases onset and recovery are sudden and

the voice when regained is clear, though perhaps at first less powerful than usual. Whilst examining the larynx through a mirror it is well to ask the patient to cough: if the cords remain separated during attempted phonation and come together on coughing the diagnosis of functional aphonia is not in doubt.

When a patient assailed by some great emotional disturbance is "struck dumb", she is not even able to whisper, for the whole speech mechanism is paralysed. This is called "hysterical mutism".

Treatment.—In patients suffering from debility the cause should be found and treated. Predisposing local inflammatory conditions should be sought for and appropriately treated. It is well to remember that patients suffering from chronic phthisis sometimes speak very softly and may become almost aphonic.

Although in some cases of true functional aphonia the voice can be temporarily restored by powerful local stimulation, this form of treatment is not recommended for aphonia will usually recur. The most difficult patients to treat are those who have been unsuccessfully subjected to such local treatment.

The physician must be sympathetic yet firm and confident, and it is his first duty to explain that there is no serious disease. The patient may be told that the trouble results from muscular inco-ordination.

The best long-term results are obtained when the voice can be restored during the first interview, and it is imperative that no relation or friend should be in the room. A good plan is to suggest that one group of muscles in the larynx is in spasm and that without complete body relaxation it is difficult to break down this spasm. The patient may be asked to lie on a comfortable couch and told to relax as though about to go to sleep. It is surprising how many patients will in fact go straight into a semi-hypnotic state. The "laryngeal box" may be moved from side to side across the vertebral column and suggestions made that by breaking down the spasm in this way the voice will be fully restored. More often than not when told to rouse herself and recite "God Save the Queen" the patient will do so in a normal voice. Should the voice be not fully restored the physician must retain his attitude of complete confidence, and assure his patient that there has been encouraging improvement, and that restoration of normal function can and will be attained in a short space of time. When the voice is restored it should be freely exercised. Really difficult cases must be referred to an expert for psychiatric treatment.

SPASMODIC AFFECTIONS

SPASM OF THE GLOTTIS

Spasm of the laryngeal muscles produces adduction of the cords, for, though the abductors are probably affected, they are overpowered by the stronger adductor muscles.

Ætiology.—(1) In the majority of cases the spasm is a reflex set up by local irritation: foreign bodies, including the laryngoscopic mirror, irritating gases and inflammation, ulceration or tumours in or near the larynx. (2) Spasm is also caused by irritation of the recurrent laryngeal nerves by mediastinal tumours and, especially, by aneurysm. (3) Central nervous lesions, especially tabes. (4) Functional disturbances, frequently hysterical, and sometimes excited by sexual disturbances.

Symptoms.—The attacks vary much in different subjects in severity and duration. The patient clutches some support or rushes to the window. The respirations are rapid and shallow, with loud inspiratory stridor, and, in the height of a severe attack, are completely arrested with all the signs of asphyxia. The subjective sensations include a horrible feeling of anxiety, but consciousness is not lost. Many cases are less acute but persist longer, even for several hours.

Prognosis.—The attacks are practically never fatal, unless a foreign body or tumour be present.

Treatment.—During the attack amyl nitrite or chloroform may be inhaled, and ampoules of these drugs should be kept at hand. Between the attacks sources of irritation should be sought for and removed, the upper air-passages brought to a healthy condition and the general health and mode of life should receive attention. Administration of bromides may be required when the attacks recur frequently.

W. I. DAGGETT.

DISEASES OF THE TRACHEA

INFLAMMATION OR TRACHEITIS

ACUTE TRACHEITIS

Acute tracheitis may occur from any condition leading to irritation of the mucous membrane of the trachea. When it occurs as a result of bacterial or chemical agency, the whole of the upper air-passages are usually involved in greater or less degree, and the clinical manifestations are not confined to the trachea. In some cases, however, the stress of the resultant reaction falls upon this tube, and the condition therefore requires separate consideration.

Ætiology.—1. *Microbic invasion.*—This is the commonest cause. The bacteria usually found associated with tracheitis are the so-called catarrhal organisms, such as *Neisseria catarrhalis*, the pneumococcus, the Friedländer pneumo-bacillus and *Haemophilus influenzae*. It is probable that the primary organism in many cases is a virus. Frequently a streptococcus may be found, either alone or in association with one or more of those just mentioned. As with catarrhal inflammation of other parts of the upper air-passages, damp, cold or foggy climatic conditions predispose to tracheitis. It is more common in young and middle-aged adults than in infancy or in old age. Mouth-breathers are more liable to this condition. Exposure to sudden changes of temperature may be a factor in its onset.

Tracheitis may also occur as part of the clinical picture in some of the acute specific diseases, such as enteric fever, diphtheria, whooping-cough and measles. It is often a troublesome and distressing association or sequel of true influenza.

2. *Chemical agencies.*—Irritating or poisonous fumes and vapours may lead to a very acute form of tracheitis. It may therefore occur in certain occupations, unless adequate precautions are taken. The use of "poison gases" in warfare has drawn widespread attention to this form of the condition, since tracheitis was an almost constant result of certain forms of "gassing". The chief chemical irritants used in the War of 1914-1918 were chlorine, phosgene and dichloroethyl sulphide, commonly known as mustard gas. Of these the last was perhaps the most irritant to the trachea, and fatal cases invariably showed tracheal lesions. Direct inhalation of steam may also induce an acute tracheitis.

3. *Mechanical causes.*—The presence of a foreign body, or the invasion of the trachea by extension from malignant growth in adjacent structures may lead to a local or even to a general tracheitis. It is noteworthy, however, that the trachea is frequently spared in occupations involving the respiration of dusty air, which leads to deposits in the lungs and bronchial glands with resulting pneumoconioses. Although a coal miner's lungs are black, yet his trachea may be practically normal.

Pathology.—The changes found in the trachea vary from simple catarrhal inflammation to intense destructive changes with ulceration, and in some cases croupous

or membranous exudate. In the catarrhal forms, the mucous membrane shows changes similar to those in bronchitis. It is at first swollen, red and dry, the vessels running across the trachea being engorged and clearly visible. Then, owing to increased activity of the mucous glands, excessive mucoid secretion occurs and the mucous membrane becomes moist, after which resolution may take place, or the process may proceed to a muco-purulent stage, when the fluid on the membrane coheres to form yellowish or green tenacious pellets. Occasionally numerous red blood cells are extruded and the tracheal exudate becomes streaked, tinged or uniformly pinkish.

In some inflammations, such as those induced by poison gases or inhaled steam, the mucous membrane may be intensely engorged and actual destruction may occur, involving even the deeper structures and the cartilages, so that greyish yellow sloughs result, which on separation leave ulcers. In diphtheria the characteristic false membrane composed of necrosing fibrin, leucocytes and bacilli may be found loosely attached to the mucous membrane, as in other localisations of this process. It may be primary or secondary to faucial or laryngeal diphtheria, either by direct extension or through diphtheritic infection of a tracheotomy wound.

In influenza the pink appearance of the trachea is of such constancy in fatal cases that it has come to be regarded as one of the most characteristic post-mortem changes found in this disease. The bright injection generally involves the lower half of the trachea, but it may occur along the whole length of this tube.

In whooping-cough the inflammatory reaction is usually less acute.

In typhoid fever small ulcers may occasionally be found in the trachea similar to those occurring more commonly in the larynx.

Symptoms.—Acute catarrhal tracheitis usually begins more or less acutely, like the common "cold", of which it is to be regarded as one form, with malaise, slight headache and a mild degree of fever, the temperature being usually between 99° and 100° F., rarely 101° F. The patient soon experiences a sensation of irritation behind the sternum, rapidly leading to a harsh, dry cough of noisy character. The cough aggravates the retrosternal discomfort, which develops into a sensation of rawness or soreness, making the cough very painful and distressing. If the larynx is involved at the same time, the voice becomes hoarse and sometimes lost, or reduced to a raucous whisper. In tracheitis alone the voice is usually unaffected. After from 12 to 24 hours the condition passes into the mucoid stage. The cough becomes looser and less painful, and small pellets of tenacious mucus are coughed up, usually greyish or black in town-dwellers, whitish in those in rural conditions; in either case, the mucus may be streaked with blood or even tinged a uniform pink colour; in the more acute forms it sometimes becomes yellow and more purulent. In the mucoid stage, the retrosternal soreness becomes less, the constitutional symptoms abate, while the temperature subsides and becomes subnormal. The patient often feels weak and out of health for some days, and is sometimes left with a noisy morning cough and tracheal irritation which may last for days or weeks. The aspect of the patient shows nothing characteristic. There is the general appearance of fever, malaise and discomfort. The rise of temperature and increase in pulse-rate are usually moderate. In the early stages physical examination of the chest shows no abnormality, but when exudation occurs a coarse wheeze may be audible over the trachea, particularly when the patient takes a deep breath or just before a cough occurs.

Diagnosis.—The association of catarrhal symptoms with a dry, harsh cough and retrosternal soreness, without signs of bronchitis, is almost pathognomonic. In some cases the diagnosis can be established with the laryngoscope or by endoscopy, but in most the discomfort which these examinations entail is unnecessary.

Prognosis.—This is almost invariably good, except in debilitated subjects or in those with cardiac or renal disease, in whom the process may spread to the larynx,

bronchi or lungs. The usual course is from 2 days to a week, though cough and expectoration may persist for days or weeks. The condition may become chronic. To some extent the prognosis depends upon the care and treatment in the initial stage. Cases that are neglected are liable to become chronic.

Treatment.—The prophylactic and remedial treatments of acute tracheitis are practically identical with that of acute bronchitis of the larger tubes. Even in mild cases the patient should go to bed, though this may be necessary only for 1 or 2 days, but he should keep to his room till his temperature has become normal. There may be less need for expectorants than in bronchitis, and a simple saline diaphoretic mixture, with the addition later of tinct. ipecac. and tinct. opii camphorata, may be all that is necessary. Sedative inhalations, such as vapor benzoini, are useful, and counter-irritation to the sternal region is comforting to the patient. When a chronic noisy cough develops a mixture containing small doses of apomorphine and tinct. chloroform et morphin. co. often gives relief, or codeine linctus B.P.C. Penicillin is often of value given by inhalation or in severe cases by injection (pp. 8 and 9).

When tracheitis occurs as part of some specific disease, such as diphtheria or influenza, the treatment should be that appropriate to the primary disease.

In "gassing", every effort should be made to relieve the distressing and painful symptoms, and for this purpose morphine may be required. Various inhalations may be tried, and useless cough should be checked by sedative mixtures or by a linctus of heroin, morphine or codeine.

CHRONIC TRACHEITIS

Ætiology.—Chronic tracheitis may follow an acute attack, or it may develop insidiously in patients suffering from chronic laryngitis or bronchitis. Inhalation of cigarette smoke is a not infrequent cause. It is also sometimes a sequel of chronic rhinitis, especially of the atrophic form or ozæna. A certain degree of chronic tracheitis accompanies the specific lesions of syphilis and tuberculosis, which are described below.

Pathology.—Various degrees of chronic inflammatory lesions may be found. In chronic catarrhal tracheitis, the vessels are distended or engorged, and the mucous membrane of the trachea becomes thickened and more or less covered with mucoid or muco-purulent secretion, the histological changes being those of chronic catarrhal inflammation, namely, shedding of the ciliated epithelial cells, overactivity of the mucous glands and sometimes thickening and induration of the submucous tissues from proliferative changes. A condition of perichondritis of the tracheal cartilages may, in this case, be observed, and this may result in a mammillated appearance in the internal aspect of the trachea. In ozæna, crusts similar to those in the nose and pharynx may form on the tracheal mucosa.

Symptoms.—The symptoms of chronic tracheitis are similar to those of the acute form. There is a sense of discomfort and irritation about the trachea and a chronic, almost dry cough, often worse in the morning. There is generally some scanty, sticky expectoration, mucoid or muco-purulent, darkened by carbon particles and occasionally blood-tinged.

There are practically no physical signs of this condition, except that the tracheal changes can be observed by the laryngoscope or by endoscopy of the trachea.

Diagnosis.—This is concerned chiefly with its differentiation from chronic changes in the trachea due to syphilis, tuberculosis or leprosy and confirmation that it is not caused by the presence of new growth. It must largely be made by endoscopic examination.

Prognosis.—The prognosis depends upon the cause. When this can be removed as by treatment of predisposing conditions in the nose and throat, the outlook is good.

When the tracheitis is due to other conditions, such as syphilis and tuberculosis, it depends upon the situation and extent of the other lesions and upon the treatment adopted.

Treatment.—This is, in its main features, similar to that of acute tracheitis, but climatic treatment may be of great importance. The patient may perhaps spend the winter months in a warm or equable and clear climate with great advantage. When other conditions are concerned, such as *ozæna*, syphilis or tuberculosis, the treatment appropriate to them should be employed as well.

CYSTS AND TUMOURS

These are rare conditions, but require careful consideration.

CYSTS

Owing to weakening of the wall of the trachea, local bulging may occur, giving rise to a cystic, air-containing swelling in the neck, in direct communication with the lumen of the trachea. Such cysts are known as "tracheoceles" or "aerocèles". They are resonant to percussion and can often be temporarily reduced by pressure.

Small retention cysts may occur in the posterior wall of the trachea, from obstruction of the ducts of the mucous glands as they pass through the trachealis muscle. They are of pathological interest only, and do not give rise to symptoms.

SIMPLE TUMOURS

The most important is papilloma. It occurs chiefly in children and is usually pedunculated. When it grows in polypoid form it may lead to obstruction of the trachea low down, in which case tracheotomy may fail to give relief, and death results unless the tumour can be removed by endoscopic methods.

Other innocent tumours occur, but are rare. They include enchondrosis from localised overgrowth of cartilage, multiple enchondromata, and osteoma from ossification of a pre-existing enchondroma. Lipoma and aberrant thyroid tumours may occur, but are very rare.

Symptoms.—These tumours produce varying degrees of tracheal obstruction, and can usually only be recognised by endoscopy. Treatment is considered under that of tracheal obstruction.

dysphagia and sometimes laryngeal paralysis reveal the origin of the tracheal symptoms when they occur. In this case copious frothy mucoid expectoration is frequent, and when ulceration develops with perforation, food particles may enter the trachea excite cough and soon lead to inhalation broncho pneumonia or gangrene. When the growth is near the bifurcation, urgent dyspnoea is the rule, and spasmodic attacks may occur, causing extreme distress. In most cases of tracheal growth the characteristic clanging brassy cough (gander cough) of tracheal obstruction can be heard. The trachea may be pushed to one side and its lumen distorted and obstructed by growth in the cervical glands or in the thyroid gland. In mediastinal new-growth invading the trachea, the pressure signs and symptoms characteristic of that disease usually render the explanation of the tracheal symptoms apparent.

Diagnosis—Intratracheal growths have to be differentiated from other causes of tracheal obstruction, and the diagnosis is considered in detail under that condition. Endoscopy affords valuable confirmation if it is practicable or desirable. In oesophageal and mediastinal new growths invading the trachea, radiographic examination may assist in diagnosis.

Course—This is generally rapidly progressive.

Prognosis—This is hopeless, death occurring from asphyxia or from some complication or by asthenia.

Treatment—Treatment can be palliative and symptomatic only. In obstruction, it may be possible in rare cases to give temporary relief by a low tracheotomy, but, as a rule, this is impossible, owing to the presence of obstruction below any point where the trachea is accessible.

THE INFECTIVE GRANULOMATA

SYPHILIS

The trachea may be affected in both the congenital and acquired forms.

In congenital syphilis, a progressive cicatrization may occur, leading to stenosis. In acquired syphilis, during the secondary stage, the mucous membrane of the trachea may become generally hyperæmic, or small raised mucous patches may develop locally. In the tertiary period, gummata may occur in the trachea, the commonest site being towards the lower end. Degenerative processes, leading to necrosis and softening eventually result in ulceration, sometimes with local sloughing of parts of the tracheal rings. In the process of cicatrization a progressive stenosis may develop.

Symptoms—Symptoms are those of chronic tracheitis and tracheal irritation in both the secondary and tertiary manifestations, but in the latter, signs of tracheal stenosis may develop when scarring and healing are in progress. Laryngeal involvement occurring at the same time tends to distract attention from the tracheal lesions or to obscure them.

Diagnosis—The diagnosis of syphilis of the trachea depends upon a careful study of the history of the case, indications of tracheal irritation, laryngoscopic or endoscopic examination, the coexistence of other manifestations of syphilis, and in their absence, a positive Wassermann reaction.

Prognosis—If the condition is recognised early, excellent results may be obtained by treatment, but it is obvious that where deep destructive changes have resulted medicinal measures can only palliate.

Treatment—Antisyphilitic treatment should be administered vigorously. In cases of stenosis of the trachea from cicatrization, dilatation of the stricture by means of bougies introduced through an endoscope may be practicable and afford useful help.

TUBERCULOSIS

Tuberculosis of the trachea may be found post mortem in advanced cases of pulmonary tuberculosis, usually in those with extensive laryngeal involvement. Primary tracheal tuberculosis is unknown. Secondary lesions in the trachea and bronchi are found not infrequently on systematic endoscopic examination.

Pathology.—Tuberculous lesions may occur at any part of the trachea, but they are more frequent in the lower part and on the posterior wall. When they occur they are usually numerous. There may be some general hyperæmia, or small tubercles, varying in size from a pin's head to a split pea, may be visible. Later, superficial ulceration occurs, forming irregular punched-out ulcers. Occasionally, the process may extend deeper, and erosion of the cartilages may occur, with the formation of sinuses and even fistulous communication with the œsophagus.

Symptoms.—Since tracheal tuberculosis is usually a late manifestation of advanced disease, its clinical indications are slight and are usually obscured by the more obvious laryngeal and pulmonary symptoms and signs, though if the process extends deeply and produces sinuses and fistulous tracks, it may become apparent. The actual tracheal symptoms are those of cough and retrosternal soreness.

Diagnosis.—This condition has to be distinguished from other chronic tracheal lesions, and a diagnosis can only be made from a careful review of the history, the general evidence of tuberculous disease, and by the tracheal involvement which may be visible by endoscopy.

Treatment.—American observers have treated the lesions by cauterisation with silver nitrate. Streptomycin and isoniazid are usually effective.

LEPROSY

In some cases of this disease, granulomatous lesions occur in the trachea, and these may eventually give rise to tracheal stenosis, owing to the contraction of new-formed fibrous tissue. The diagnosis can only be made from the occurrence of tracheal symptoms in a case with established lesions of leprosy in other parts.

The treatment is symptomatic.

SCLEROMA

Although in most cases this condition affects the nose only, scleromatous lesions may be found in the trachea as a pathological curiosity. The disease in any form is rare in England, and occurs chiefly in Poland and Austria. The nodules of granulomatous tissue in the trachea may cause partial obstruction mechanically, or, on contraction, lead to actual stenosis.

TRACHEAL OBSTRUCTION

Obstruction to the lumen of the trachea may be produced by foreign bodies, by conditions originating in the trachea, and by pressure from without.

FOREIGN BODIES IN THE TRACHEA

The commonest route by which foreign bodies enter the trachea is through the mouth and larynx, in the acts of breathing, laughing, yawning, sighing, or before and after coughing, when food or some foreign substance is in the mouth. A piece of bone, a stud, button, false teeth, chewing gum, peas, articles of food, nuts, grains of wheat, beads or blades of grass are among the substances which may gain entrance

to the trachea in this manner. Surgical operations in the mouth and throat may lead to the inhalation of a tooth, a piece of tonsil or a mass of adenoid tissue. Material vomited from the stomach, such as food, blood clot or intestinal worms, may be inhaled into the trachea. A large blood clot in hæmoptysis may temporarily obstruct it. Foreign bodies, such as small projectiles embedded in old wounds of the neck, pieces of new-growth or tuberculous glands may also gain access by ulceration through the tracheal wall.

Unless it becomes impacted, or is too large to enter one of the two main bronchi, a foreign body rarely remains long in the trachea. It either causes death with dramatic rapidity, is coughed out again, or passes down into one or other of the large bronchi or their secondary divisions, where it produces results which are described in the section on diseases of the bronchi.

Symptoms.—These depend upon the mode of entry, the size of the foreign body, and the degree of obstruction to the air current which it induces, but in general the tracheal symptoms are less urgent than those of laryngeal obstruction, and less serious than those of obstruction of one or other main bronchus. There may be intense dyspnoea, with great discomfort and alarm during the actual passage through the larynx of a small foreign body, especially if it is temporarily arrested there; but when it enters the trachea there is an almost instantaneous cessation of the acute distress, though some degree of dyspnoea may persist. The type of dyspnoea is inspiratory in the main, though a minor degree of expiratory difficulty may be apparent if the foreign body is of considerable size. There may be a definite stridor with both phases of respiration, but it is more pronounced in inspiration. If the foreign body remains loose in the trachea, which may occur if it is rounded and too large to engage in one of the main bronchial divisions, a sound of vibratory character may be heard on auscultation of the trachea, sometimes described as the *bruit de grettement*. This may be produced by friction of the foreign body against the tracheal wall, or more commonly by the air passing over it during respiration. A paroxysmal cough may occur, caused by the foreign body irritating the sensitive posterior wall of the trachea, and during such an attack the foreign body may be forced up to the larynx, obstruct it, or cause reflex spasm with intense dyspnoea and cyanosis and a risk of suffocation, unless it drops back, is coughed out, or removed. When sudden rupture of caseous material into the trachea occurs, the lumen may be blocked and death take place rapidly.

Diagnosis.—The history of disappearance of some object from the mouth during coughing, breathing or laughing should give rise to suspicion of an inhaled foreign body, and this may be confirmed by seeing the object directly by endoscopy, or indirectly by means of the radiograph.

Course.—A foreign body impacted in the trachea may give rise to septic inflammation of its walls, with subsequent cicatrization after removal, or it may lead to secondary infective processes in the lungs, such as purulent bronchitis and broncho-pneumonia.

Prognosis.—This depends in the main on the nature of the foreign body, and the time elapsing before its removal. An irregular, rough or soft foreign body is more likely to induce septic complications than a smooth, hard substance. Apart from rapidly fatal results, the prognosis is better with intratracheal foreign bodies than with those reaching the bronchi. If removal is effected within 24 to 36 hours, recovery is usually rapid and complete.

Treatment.—Treatment consists in rapid removal with as little damage to the trachea and larynx as possible. This may be effected by means of forceps passed through a bronchoscope, or rarely by tracheotomy alone, when the foreign body may be coughed out through the opening or be easily removed by forceps. Inversion of the patient in the hope that gravity may assist the expiratory efforts of cough is dangerous and should only be attempted after tracheotomy has been performed. Where

rupture of a caseous gland or softening new-growth occurs into the trachea, an immediate tracheotomy may be necessary.

OBSTRUCTION FROM CICATRISATION OF THE TRACHEAL WALLS

Ætiology.—This may result from any condition leading to ulceration of the tracheal walls, with subsequent healing, such as a syphilitic gumma, or less commonly other granulomata, such as tubercle, leprosy or scleroma. Another cause is cicatrization from wounds of the trachea, accidental, suicidal or after tracheotomy, when the incision has been made too near the cricoid, or when the wound has become infected or the tube left in too long. Scarring from damage to the trachea by the inhalation of boiling or caustic liquids or even by inhaled gases may lead to stenosis.

Pathology.—The deformity of the trachea and the obstruction of its lumen depend upon the situation and the extent of the cicatricial contraction of its walls. It may be local, producing an hour-glass constriction, or involve a long extent of the tube. Occasionally, especially in syphilitic lesions, stenosis may occur at two different levels.

Symptoms.—These depend upon the degree of stenosis, the rapidity with which it develops, and the condition of the larynx, bronchi and lungs. When the stenosis is produced gradually, as in cicatrization, a degree of obstruction may result, greater than would be compatible with life if suddenly induced. In the early stages of a progressive stenosis, slight dyspnoea may be present on exertion, and during sleep a faint stridor may be audible, disappearing when the patient is awake. As the contraction progresses, the dyspnoea becomes more marked, and a definite and persistent stridor develops, at first inspiratory only, though expiration may become both noisy and obstructed. The patient may experience a sensation of obstruction referred to the neck or under the sternum, accompanied by pain and irritation, leading to cough, which may be dry, noisy and metallic, or accompanied by more or less frothy sputum, if the primary condition is associated with widespread tracheitis. The voice may lose tone and volume, and the patient talk more quietly than normal and with some evident effort. In advancing stenosis, sudden and alarming attacks of dyspnoea may occur, leading to cyanosis and threatening suffocation. These attacks are usually due to an accumulation of mucus at the site of the stenosis. The patient in advancing degrees of obstruction cannot lie down, and generally sits leaning forward with chin depressed. It may be noted that the extraordinary muscles of respiration contract forcibly, and yet the laryngeal excursions may be small or hardly noticeable, in contrast with those of laryngeal obstruction in which they are maximal. This distinguishing sign was first pointed out by Gerhardt, and is of value, but unfortunately it is not absolute and cannot, therefore, be regarded as pathognomonic. On auscultation over the trachea, a noisy roar may be audible, of maximum intensity near to the obstruction, whereas the breath-sounds over both lungs may be deficient, although the stridor may be conducted bilaterally.

Diagnosis.—Tracheal obstruction from cicatrization has to be distinguished from laryngeal obstruction, in which the symptoms are usually more acute and more urgent. Gerhardt's sign described above may also be suggestive. It has also to be differentiated from obstruction due to pressure from without (*vide infra*). The only reliable method of distinction is by direct inspection with the bronchoscope.

Course.—The course of cicatricial stenosis is usually progressive, unless arrested by treatment, and the dyspnoeic attacks become more frequent and alarming.

Prognosis.—Early syphilitic stenosis may be arrested by appropriate antisyphilitic treatment. Obstruction due to other granulomatous conditions varies with the severity and extent of the primary lesions. Caseous material or degenerated growth ulcerating

into the trachea is usually immediately fatal, or leads to death within a few days from pulmonary complications

Treatment—Rest should be advised, with avoidance of exertion, smoking and alcohol. The patient's fears should be allayed and symptomatic treatment ordered, such as sedative inhalations or a linctus to check useless cough. In syphilitic stenosis vigorous antisyphilitic treatment should be given. A low tracheotomy may be necessary for an intractable stricture high up in the trachea. In some cases where an ordinary tracheotomy cannot be performed below the stricture, it may be possible to insert Koenig's long tracheotomy tube through an opening in the trachea made above it. In other cases, dilatation of a fibrous stricture by bougies passed through an endoscope may be feasible.

OBSTRUCTION FROM EXTERNAL PRESSURE

Pressure on the trachea may occur in the neck or in the mediastinum.

Causes of pressure in the neck—Strangulation, throttling and garotting lead to death by occlusion of the trachea and suffocation. Enlargement of both lobes of the thyroid body may cause lateral compression of the trachea, until eventually its lumen is reduced to a narrow slit—the so called "scabbard trachea". Irregular or unilateral enlargements, on the other hand, cause deviation of the trachea, with kinking of its lumen. Other less common causes of compression of the trachea are enlargement of the cervical glands from tuberculosis, malignant disease, Hodgkin's disease or leukaemia. The trachea may be pressed on from behind by a foreign body impacted in the oesophagus, or by a bony tumour arising from the vertebrae.

Causes of pressure in the mediastinum—An aneurysm of the aortic arch may press directly upon the trachea at, or near, the bifurcation and cause obstruction. Similarly deep pressure may be caused by a retrosternal goitre, a persistent and enlarged thymus, or a thymic abscess, mediastinal glands enlarged from any cause, usually malignant disease, a dermoid cyst or a bony tumour originating in the sternum.

Symptoms—The symptoms are in the main identical with those of stenosis of the trachea from intrinsic causes, with the special symptoms due to the primary external condition superadded.

Diagnosis—This may be simple and obvious as in those cases due to pressure from tumours in the neck, whereas, in those due to mediastinal pressure, it is usually only possible after a careful survey of all the symptoms and is in brief identical with that of aneurysm or mediastinal new growth, to which reference should be made. In some cases radiographic examination may give valuable information.

Prognosis—This is good in obstruction due to causes in the neck other than malignant disease, but it is grave, almost hopeless, in obstruction due to mediastinal causes, with the exception of abscess, goitre, dermoid cyst and some thymic conditions.

Treatment—The treatment is that of the primary condition. In goitre and tuberculous glands in simple tumours, cysts and some thymic conditions, operation may be possible and may effect complete cure. In those due to mediastinal pressure, especially from aneurysm or new growth, treatment, in most cases, can be only palliative or symptomatic, and directed to the relief of pain, dyspnoea, cough and distress.

INJURY

Direct violence to the trachea has been known to cause rupture when the chin is raised upwards and the trachea is thereby extended.

DISEASES OF THE BRONCHI

BRONCHITIS

Inflammation of the bronchi, or bronchitis, is one of the commonest maladies and may be induced by a variety of causes. These, in the main, fall into three groups: bacterial, chemical and mechanical, similar to the causes of tracheitis, which is, indeed, in many cases, a concomitant or antecedent of bronchitis, so that tracheo-bronchitis would be a more accurate designation of the majority of cases. At the same time it should be recognised that the trachea may be alone or predominantly affected, while, on the other hand, in many cases of bronchitis of the smaller tubes, the trachea may escape, or be only slightly involved.

Bronchitis is so varied in its extent and in the form and severity of its manifestations that a satisfactory classification is somewhat difficult to formulate. We propose to consider the clinical manifestations of bronchitis according to the following classification:

1. ACUTE FORMS.—(a) Catarrhal bronchitis, (1) of the larger tubes, (2) of the smaller tubes; (b) suppurative; (c) secondary bronchitis; (d) bronchitis due to mechanical and chemical agencies; (e) fibrinous.

2. CHRONIC FORMS.—(a) Catarrhal, (b) suppurative, (c) secondary, (d) due to mechanical agencies and (e) fibrinous.

1. ACUTE BRONCHITIS

ACUTE CATARRHAL BRONCHITIS OF THE LARGER TUBES

Synonyms.—This condition is often called Bronchial Catarrh, or Acute Tracheo-bronchitis.

Ætiology.—*Predisposing causes.*—Climate undoubtedly plays an important part. Catarrhal bronchitis is rare in polar and arctic regions and near the equator, but is very prevalent in damp and foggy climates. In England, attacks are common in late autumn, winter and early spring. Owing chiefly to greater exposure, the disease occurs more frequently in men than in women. It is most common at the extremes of life, infancy and old age, but it is not infrequent at any age. Fatigue and privation play their part, and exposure to cold, wet or fog so frequently seems to initiate the attack that it is often regarded as the exciting cause. Scoliosis, kypho-scoliosis and other malformations or deformities of the chest predispose to bronchitis, and some of them are induced or aggravated by bronchitis early in life. Chronic cardiac and renal disease both render their subjects more liable to bronchitis, as do also conditions of the nose and pharynx which lead to mouth-breathing, in consequence of the inhalation of air which is unwarmed and unfiltered by the nose. There is a popular idea that a child may "cut its teeth with bronchitis" but the combination is probably coincidental.

The exciting cause is not really known. There is a suspicion that the infection is primarily viral in origin. Pneumococci, streptococci, *Neisseria catarrhalis*, staphylococci, *Haemophilus influenzae*, Friedländer's bacilli (*Kl. pneumoniae*) are found in the sputum or tissues but they are probably secondary invaders.

Pathology.—The changes induced in the bronchi are similar to those in the nasal mucosa in coryza and in the trachea in tracheitis. Three stages may be described: An initial dry stage, when there is active hyperæmia of the bronchial mucosa, with exudation into the submucous layer, causing temporary diminution of the bronchial secretion from occlusion of the mucous ducts. The second or mucoid stage is associated with copious discharge of mucoid secretion, owing to increased

activity of the mucous glands, this secretion being mixed with shed ciliated epithelial cells and scanty leucocytes. Sometimes in acute cases a few red blood corpuscles are present. The third stage is that of resolution, though not infrequently a mucopurulent stage occurs, when the sputum becomes less copious and greenish in colour from large numbers of pus cells.

In fatal cases the lung tissue may appear slightly distended and red, while the bases may be sodden from œdema. On section, the bronchi appear injected and the mucosa is swollen. On squeezing the lung, beads of mucoid fluid or muco-pus exude from the cut ends of the bronchi. There is no consolidation and the lung tissue floats in water.

Symptoms.—An attack of acute bronchitis generally begins suddenly, with malaise, aching in the limbs and a sense of oppression in the chest. If the trachea is also involved, there is the characteristic feeling of rawness under the sternum. The temperature rises, varying from 99° to 100° F. in mild cases to 103° F. in more severe ones. The cough is at first dry, irritating and ineffective, but in a few hours it becomes looser. The sputum in the early stage is scanty, tenacious and sometimes streaked with blood; it then becomes copious, mucoid and frothy in character, and is found to contain mucus, shed epithelial cells, leucocytes and red blood corpuscles. Later it lessens in quantity and may become thick, yellow and muco-purulent. With the onset of expectoration there is generally an abatement in the symptoms, the rawness under the sternum disappears and the feeling of pain or soreness about the pectoral muscles and the costal attachments of the diaphragm lessens. The febrile reaction may last only 3 or 4 days, but the cough and expectoration may go on for 10 days or longer, gradually diminishing, until they are present only night and morning, and then cease completely.

In the early stage the patient is flushed and the breathing may be slightly increased in rate, but it is rarely or never laboured, unless emphysema coexists. Vocal fremitus is unaltered, but rhonchal fremitus may sometimes be felt over one lung or both. The chief physical signs are discovered only on auscultation. The breath-sounds may be harsher and higher-pitched, particularly in infants and children, but they remain vesicular, and expiration may be prolonged. The voice conduction is unaltered. As a rule rhonchi, either sonorous or sibilant, according to the size of the bronchus in which they are produced, are audible over both lungs, and during the mucoid stage bubbling râles may be heard, especially at the bases.

Complications and Sequelæ.—Bronchitis may go on to broncho-pneumonia, lobar pneumonia, aspiration pneumonia, lobular atelectasis, fibroid induration or bronchiectasis. It may lead to chronic bronchitis, or be followed by active tuberculosis. Occasionally acute interstitial emphysema may result from violent coughing.

Diagnosis.—The diagnosis of bronchitis is usually easy, owing to the characteristic rhonchi, but it is important to differentiate primary bronchitis from bronchitis occurring as a secondary condition in acute specific fevers and other diseases.

Course.—This is variable. The patient may be convalescent in from 7 to 14 days, but cough, expectoration and a condition of debility may continue for several weeks, though, in this case, the possibility of pulmonary tuberculosis should always be considered.

Prognosis.—Bronchitis of the larger tubes is rarely fatal, except when it occurs in infants or the aged, or as a complication of advanced cardiac or renal disease.

Treatment.—**PROPHYLACTIC.**—This consists in the avoidance of stuffy, ill-ventilated rooms and places of entertainment when catarrhal infections are rife. To mouth-breathers, steps should be taken to deal with the conditions of the naso-pharynx inducing this habit, and instruction in normal breathing given. To dusty occupations, suitable measures should be taken to minimise the irritant particles in the air, as is now done in most factories and workshops. Where poisonous gases have to be encountered, some form of efficient gas-mask should be utilised.

Vaccines have been and still are widely used in the prophylactic treatment of catarrhal infections. They have their enthusiastic adherents amongst doctors and patients, but there is no objective evidence of their efficiency and much to the contrary.

CURATIVE.—No matter how mild the attack may be at the onset, the patient should be kept in bed. This may only be necessary for 1 or 2 days, but he should keep to his room till his temperature has returned to normal. The room temperature should be kept at 60° to 65° F. While the temperature is raised, the diet should be simple, adapted to the patient's appetite and the febrile condition. The patient should take plenty of fluids and hot, warm drinks are often welcome. The air of the bedroom may be moistened by the use of a steam kettle in the dry stage, but steam tents should not be used. Hot compresses over the sternum sometimes help to relieve the raw soreness. The inhalation of steam is comforting, and vapor benzoini—60 minims to the pint of water at 160° F., or vapor pini, 120 minims to the pint—is often added to the water. During the dry and painful period of acute bronchitis a sedative linctus may be given. Once expectoration starts, mixtures containing ammonium chloride or carbonate combined with squills and flavoured with syrup of tolu or of Virginian prune may be given. Sedatives may be necessary at night—Dover's powder, gr. 10, with or without aspirin, barbitone, gr. 5 to 10, or chloral hydrate, gr. 10 to 20 are all suitable. Opium and its derivatives are best avoided. Antibiotics are not usually necessary or required, although they may cut down the secondary infection and are often given as a routine to elderly patients. The older the patient, the longer should be the convalescence. Premature return to normal life may be followed by a relapse or perpetuation of the bronchitis for weeks.

When bronchitis occurs as a part of some specific disease, such as diphtheria or influenza, the treatment should be that appropriate to the particular disease.

ACUTE CATARRHAL BRONCHITIS OF THE SMALLER TUBES

Synonym.—Capillary Bronchitis.

It is open to question whether this condition exists as a separate entity. When the finer bronchi and bronchioles are inflamed the alveoli invariably become involved, since very little swelling of the bronchiolar walls is sufficient to occlude the lumen of the tube, with the inevitable production of an area of lobular collapse. The transition from this condition to actual lobular pneumonia is a very small one. In any case, the causes, the symptoms and the treatment of capillary bronchitis and broncho-pneumonia are identical (see Broncho-pneumonia).

ACUTE SUPPURATIVE BRONCHITIS

Synonyms.—Sometimes called Acute Purulent Bronchitis.

This condition was brought into prominence during the War of 1914–1918. In 1916 and 1917 it appeared in epidemic form amongst the British troops in England and France. Although it was then regarded by some observers as a new disease, it is more probable that it was, in reality, an epidemic form of a condition usually rare and sporadic and previously termed "suffocative catarrh".

Ætiology.—*Predisposing causes.*—The exceptionally severe winter of 1916–1917, together with conditions of overcrowding in huts and billets, were undoubtedly concerned in the epidemic just mentioned. The condition affects young adults chiefly, and is much more common in men. Over-exertion, fatigue and debility predispose to it, but the disease may occur in robust and healthy persons. A history of chill may be given, but often no obvious cause can be discovered.

Exciting cause.—The organisms usually found are the pneumococcus and *H. influenzae*, the latter being reported in 90 per cent. in some series of cases. *N. catarrhalis* is also sometimes present.

Pathology.—A very intense inflammation occurs in the medium-sized and small bronchi, leading to an exudate rich in leucocytes. The inflammatory process may extend to the alveoli, which then contain a fibrinous fluid, with entangled red cells. The condition occurs in both lungs and is usually almost universal, no portion being spared. Post mortem the lungs are heavy and red in colour. On section the bronchi are found to contain a thick yellow purulent fluid. Small areas of collapse and sometimes of broncho-pneumonic consolidation are seen, and there is usually oedema of the bases. Plastic pleurisy is not infrequent, and the glands at the root of the lungs are enlarged.

Symptoms.—The onset is usually abrupt, often in young people apparently in robust health. A definite chill may occur, or only coryza and general malaise, with aching of the muscles. The temperature rises quickly and may reach 104° F. early in the disease. A cough soon develops and extreme dyspnoea is a characteristic feature. Expectoration starts early, often on the second or third day. At first it may be streaked with blood, but it soon becomes yellowish green and nummular; it consists of almost pure pus; there is often as much as 5 or 6 oz. in 24 hours. In most instances there is great prostration. In grave cases the patient becomes unconscious and loses control of the sphincters.

There is intense cyanosis, the face, lips and ears being purple. The respirations are rapid, 30 or 40 per minute, and the accessory muscles are often in full action. Palpation and percussion may not show any abnormality though slight dullness is sometimes present at the bases. At first no signs may be discovered on auscultation, but soon the breath-sounds become largely obscured by medium-sized bubbling râles, often audible from apex to base, both front and back. The pulse is frequent, the right heart may dilate and the heart-sounds become weak.

Complications and Sequelæ.—In severe cases recurrent bronchitis, broncho-pneumonia, fibroid disease or emphysema may follow.

Diagnosis.—The early occurrence of marked dyspnoea and cyanosis, the expectoration of copious pus, and the widespread râles without dullness are very suggestive of acute suppurative bronchitis. The disease must be differentiated from other conditions described as acute suffocative catarrh that are associated with extreme dyspnoea and cyanosis.

Acute pulmonary oedema is usually afebrile, and the sputum is albuminous, frothy and copious. The condition leading to it, such as cardiac or renal disease, may be apparent.

Capillary bronchitis or broncho-pneumonia may give rise to difficulty, but in these conditions the sputum is scanty, tenacious, sometimes rusty and but rarely purulent; moreover, cyanosis and dyspnoea develop late and depend upon the extent of the disease and the condition of the right side of the heart.

Pneumonia of the wandering type may simulate this condition, but the character of the signs, with dullness and tubular breathing, and the rusty sputum, usually render diagnosis easy.

Course.—In favourable cases complete restoration to health results. In severe cases the course is rapid, the patient becomes comatose from toxæmia, expectoration ceases and death occurs from exhaustion in 2 or 3 days from the onset. In other cases the disease may last for 6 weeks and proceed to recovery or death.

Prognosis.—This is very grave. The mortality is high, often as much as 50 per cent. Cases extending to 3 weeks or more with swinging temperatures usually recover.

Treatment.—The disease is highly infectious and the patients should be isolated. In the 1916, 1917 and 1918 epidemics death occurred earliest and most frequently in those who walked about while infected. Immediate rest in bed is essential and oxygen should be given from the beginning by double nasal catheter or B.L.B. mask. Penicillin or other suitable antibiotic, as indicated by the sputum, should be tried from the start.

SECONDARY BRONCHITIS

Ætiology.—Bronchitis, usually of catarrhal type—indistinguishable as regards symptoms and signs from primary acute catarrhal bronchitis—occurs as a definite part of many acute infectious diseases and as a complication in others. Among these may be mentioned measles, whooping-cough, influenza, the enteric group, small-pox, diphtheria, malaria and plague. Acute nephritis of infective origin is often accompanied by acute bronchitis. Other conditions associated with bronchitis are pulmonary tuberculosis, glanders, secondary syphilis, pleurisy and gunshot wounds.

Diagnosis.—Bronchitis is easy to recognise, but it is important not to overlook the fact that it may not be the primary condition. In all cases of bronchitis in the early stages, the possibility of a primary acute specific infection should be borne in mind. The diagnosis is also of importance in regard to treatment—for example, in malaria, nephritis and syphilis, in which treatment directed to the primary condition may be more helpful than the ordinary treatment of catarrhal bronchitis.

BRONCHITIS DUE TO MECHANICAL AND CHEMICAL AGENCIES

Ætiology.—*Mechanical*—Attacks of acute bronchitis may be caused by the inhalation of dust-laden air. In occupations where the worker is liable to inspire fine particles of carbon, silica, steel, iron, asbestos or kaolin, acute bronchitis may result, but more often these conditions lead to chronic bronchitis and pneumoconiosis. Some industrial dusts are especially irritating—manganese dioxide and basic slag and certain fine wood dusts from West Africa are examples of these.

Chemical—Acute bronchitis may follow the inhalation of chemical irritants, either as a result of occupation, accidents, attempts at suicide or the use of poison gases in warfare. Special attention has been drawn to this subject by the large number of cases of “gassing” dealt with in the War of 1914–1918. Death not infrequently occurred, much acute suffering was caused, and some permanent damage has resulted in many cases which recovered. Mustard gas produces its chief effects upon the skin, the eyes and the bronchi. A fibrinous exudate forms on the mucosa as a false membrane, which separates as a slough. The suffocative gases chlorine and phosgene affect the alveoli primarily and more intensely. Chlorine inhaled in a concentration of 1 in 10,000 causes a rapid alveolar flooding with a serous and highly albuminous fluid, and if the victim does not die at once he is liable to suffer from an acute bronchitis. A condition called bronchiolitis fibrosa obliterans may occur as a sequel. It is often associated with asthmatic dyspnoea. Lewisite produces much the same effect on the lungs as mustard gas. The only noxious gases likely to be met with in civilian life are nitrous fumes, chlorine and ammonia.

Symptoms.—These are similar to those of acute catarrhal bronchitis, but there is great pain, distress and almost constant cough, often with copious expectoration.

The treatment is referred to under the heading of Tracheitis, and is, in the main, symptomatic and directed to the relief of pain, useless cough and distress. If there is cyanosis, oxygen should be given continuously if necessary by double nasal catheter, B. L. B. mask or oxygen tent.

ACUTE FIBRINOUS BRONCHITIS

Synonym.—Acute Plastic Bronchitis

Definition.—A comparatively rare acute disease in which there is inflammation of the bronchi, with the formation of casts. These may be hollow or solid and are coughed up in the expectoration.

There are some who deny that this is a disease *sui generis* and who maintain that it is but a condition found occasionally in bronchitis. It appears to have been known to the ancients and in more recent times was well described by Osler and McCrae and more recently by Davidson. Both these accounts describe it as a separate entity.

Ætiology.—It is more common in males, and is met with both in children and

in adults. It may begin as a primary catarrhal bronchitis, or develop as a complication of enteric fever, measles or pulmonary tuberculosis. Such organisms as the pneumococcus or a streptococcus may be found in the casts.

Pathology.—The casts may involve the main bronchi only, or more frequently the smaller ones and the bronchioles. They are greyish white, solid or tubular, and when large, bear the impress upon their exterior of the bronchial walls in which they have been enclosed. Thus, when a cast extends up to the lower portion of the trachea, the indentations made by the tracheal rings may be seen impressed upon it. The fine terminations generally show a spiral moulding. Chemically, they consist of fibrin or of fibrin and mucin. Post mortem the casts may be seen in some places *in situ*; in other areas the bronchi from which they have been expelled may be recognised. The bronchial mucous membrane is at times acutely inflamed, red in colour, with the lining epithelial cells desquamating, or it may appear pale and unaffected. There is usually a certain degree of emphysema, and there may be collapse of lung tissue beyond the site of obstruction.

Symptoms.—The disease generally begins somewhat abruptly with a cough and malaise. In the course of a few days the patient becomes considerably worse, dyspnoea develops and a certain degree of pyrexia, but the temperature is often not more than 99° or 100° F. The dyspnoea becomes more intense, and is the prominent and all-important symptom. The face is seen to be cyanosed, the alæ nasi and the accessory respiratory muscles are in violent action, sometimes with retraction of the intercostal spaces. There may be diminished movement of the chest, either bilateral or unilateral. If there is unilateral pulmonary collapse the heart may be slightly displaced towards the same side. Vocal fremitus may be normal or locally diminished. The percussion note is somewhat hyper-resonant over the anterior chest-wall, but behind there may be some degree of dullness over one or other lobes. If the bronchi are unilaterally affected there may be dullness limited to one lower lobe, with diminution of air entry and no adventitious sounds. Vocal resonance over the affected area is lessened. There is usually some diffuse bronchitis, as indicated by the presence of rhonchi or râles. Marked stridor is sometimes heard with respiration. A special sign, the "bruit de drapeau", has been described when the cast lies free in the bronchial lumen. It is a dry clicking sound, caused by the flapping of the cast against the wall of the bronchus as the air passes over it. The ordinary sputum does not show any peculiarities. It may, however, show Curschmann's spirals, Charcot-Leyden crystals and eosinophil cells, and it may be absent until the crisis occurs. This consists in the expectoration of the cast after a violent fit of coughing. The cast may be stained with blood, or there is sometimes actual hæmoptysis. The peculiar nature of the expectoration often escapes notice, unless it is examined by floating in water, when a large intact cast is revealed. The dyspnoea ceases immediately after the cast has been expelled.

Complications and Sequelæ.—Emphysema may occur as the result of the violent coughing, or the disease may become chronic, recurring at intervals of varying duration. The most serious complication is laryngeal obstruction, caused by the cast becoming impacted between the vocal cords.

Diagnosis.—The stridor and respiratory obstruction are suggestive of oedema of the glottis, but auscultation will show that the site of the lesion is lower down the respiratory tract. Asthma, and all causes of laryngeal and tracheal obstruction, must be excluded. The dyspnoea and the presence of signs localised to one lobe may suggest an active lobar collapse, or a lobar pneumonia, but the dyspnoea is more intense than is met with in either of these conditions. Casts are expectorated in diphtheria, pneumonia, chronic disease of the heart, pulmonary tuberculosis and hæmoptysis. The casts of acute fibrinous bronchitis are firmer than those found in these affections, and are expectorated in long pieces, showing the many branches and bifurcations of the bronchial tree.

Course.—The disease is generally self-limited, terminating with the separation and expectoration of the cast. The acute stage does not, as a rule, continue for more than 12 to 24 hours.

Prognosis.—The immediate outlook is fair. Death may occur in the first attack, or recurrences may take place, which lead to an increasing degree of emphysema, with its usual results. The ultimate prognosis is, therefore, not good.

Treatment.—The patient should be kept in bed and treated as a case of acute bronchitis. Inhalations of medicated vapours often afford relief. Potassium iodide is believed to expedite the separation of the cast. Bronchoscopic removal is sometimes necessary and tracheotomy instruments should be available in case of laryngeal obstruction.

2 CHRONIC BRONCHITIS

Chronic bronchitis is perhaps even more difficult to classify than the acute varieties, each one of which may have its counterpart in chronic form, so that the same classification may be followed. At the same time it must be admitted that, especially in the catarrhal forms, the clinical manifestations are somewhat varied.

CHRONIC CATARRHAL BRONCHITIS

Ætiology.—The causes are practically identical with those of the acute form, of which it is in most cases a sequel.

This affection may commence at any age, although it is more common in middle life and with advancing years. Men are more frequently affected than women. It seems also to have a special incidence in some families. It is more common in damp and foggy climates, and is favoured by urban conditions and by dusty occupations. It starts each winter with a more or less acute catarrhal attack, but each year the summer intermission becomes shorter, until the bronchitis persists throughout the year. It tends to produce emphysema and is aggravated in turn by this condition. It is especially favoured by cardiovascular lesions, such as valvular defects and arterial disease, also by gout, chronic nephritis, syphilis and alcoholism. Conditions associated with chronic cough predispose to it, notably emphysema, asthma, arrested pulmonary tuberculosis, mouth breathing and cigarette-smoke inhaling.

The bacteria found are practically identical with those in acute bronchitis, the commonest being the pneumococcus, Friedländer's pneumobacillus *N. catarrhalis*, streptococci and staphylococci. Mixtures of two or more of these may be present.

Pathology.—The bronchi show chronic inflammatory changes of a catarrhal nature. The walls are thickened from chronic hyperæmia and also from productive changes in the connective tissues. The mucous glands may be hypertrophied or atrophied, and there may be widespread desquamation of the ciliated epithelial lining of the bronchi. In long-standing cases there is usually some peribronchitis leading to cylindrical bronchiectasis and distortion of the bronchi by fibrosis. There is almost invariably a greater or less degree of emphysema, which may be generalised or only marginal. Post mortem, the lungs are generally red and somewhat engorged, but if much emphysema has resulted they may be paler than normal. On squeezing the lung after section, pus or muco-pus exudes from the cut bronchi, and there is usually some evidence of œdema at the bases.

Symptoms.—A patient with chronic bronchitis complains of cough, expectoration and shortness of breath on exertion. The cough varies greatly in its severity. During the warm weather the patient may be completely free, and yet suffer for years from a winter cough. It may occur frequently throughout the day and in attacks at night, or only in the mornings and evenings.

The expectoration varies considerably in quality and quantity, so much so that

the old classifications of chronic bronchitis were based on this factor. Thus, there may be practically no sputum or only small tenacious pellets, the "*crachats perlés*" of Laennec; on the other hand, there may be a profuse expectoration resembling unboiled white of egg diluted with water. Usually the sputum is mucous or mucopurulent and contains greyish-black particles mixed with a frothy fluid. The dyspnoea is largely due to the accompanying emphysema, and so indicates the degree of chronicity of the disease. At first the patient may only notice that he gets out of breath on going upstairs or on mounting slopes, but later even walking on the level causes dyspnoea.

Slight rises of temperature occur in the acute exacerbations of the catarrhal process. Slight cyanosis is frequently observed, especially after exercise, when the accessory respiratory muscles are called into play. Sometimes rhonchal fremitus is felt. Movement of the chest is restricted by emphysema, and the percussion note then becomes hyper-resonant. On auscultation, expiration is prolonged and sonorous or sibilant rhonchi are heard all over the lungs, with bubbling râles if there is thin secretion in the smaller bronchi. On the other hand, rhonchi may be scanty or only occasionally heard. Voice conduction is unaffected. The fingers may be slightly clubbed, and further evidence of venous obstruction may be apparent in the dilated venules on the cheeks or along the costal attachments of the diaphragm.

Complications and Sequelæ.—The following changes may occur in the lungs—peribronchial fibrosis, bronchiectasis and emphysema. Asthma or attacks of bronchial spasm sometimes form a complicating factor in chronic bronchitis, especially in the cases of so-called bronchorrhœa. Emphysema may lead to pulmonary hypertension and right heart failure. Late in the disease, as the result of the cyanosis, a peculiar form of confusional delirium is met with, which is worse at night.

Diagnosis.—Chronic bronchitis must be distinguished from pulmonary tuberculosis, bronchitis secondary to heart failure, and from bronchiectasis. In tuberculosis with bronchitis there is generally wasting, and often flattening of the chest-wall, owing to fibrosis of the lungs. In all cases where the summer intermission of the symptoms fails suddenly rather than lessens gradually, tuberculosis should be suspected. The diagnosis is clinched by the presence of tubercle bacilli in the sputum. In bronchitis secondary to heart failure, in addition to the cardiac signs, the râles in the lungs are chiefly basal and the rhonchi are not so universally distributed. In bronchiectasis the signs are usually characteristic and often limited to one lobe. The radiograph will afford useful aid in diagnosis.

Course.—The disease once firmly established, unless relieved by suitable climatic treatment, remains chronic and becomes progressively more severe as further damage is wrought in the lungs with each hibernal exacerbation. As the emphysema develops, a vicious circle is initiated, the aerating power of the lungs diminishes and finally cardiac failure ensues.

Prognosis.—The immediate prognosis is good, the ultimate is bad. Much depends upon the patient's social condition and opportunities for treatment, especially in respect to climate. The expectation of life of a patient suffering from chronic bronchitis is considerably shortened.

Treatment.—Those subject to chronic bronchitis derive benefit from life in a warm, equable climate. In England the south-western districts are best. Well-to-do patients can sometimes prolong their useful life by wintering in warmer climates. High altitudes should be avoided if emphysema is present or if there are cardiac complications. Exposure to wet and chill is dangerous. The question of occupation is often difficult. Much time should be spent out of doors, provided that the patient is not exposed to the inclemencies of the elements; and, further, the work undertaken must not involve severe muscular efforts, or the inhalation of dusty or irritant particles.

In England it is difficult to find an outdoor occupation conforming with these

desiderata, consequently light indoor work in a good atmosphere should be advised. Clothing should be warm but light, and afford special protection to the chest without overloading, as some patients are liable to do. Excesses in diet are to be avoided, also alcohol and heavy smoking. The general nutrition should be well maintained, and many patients, especially those of spare habit, seem to derive great benefit from cod-liver oil during the winter months.

If cough is troublesome and expectoration tenacious or scanty, various combinations of expectorant remedies are useful, such as ammonium carbonate or chloride, tinct. *ippecacuanhæ*, preparations of squills or senega, with *tolu*, liquorice or Virginian prune as flavouring agents. A simple saline mixture such as *R* Sodii bicarb, gr 10, sodii chlorid, gr 3, sp chlorof, min 5, aquam anethi dest ad fl oz 1, taken with an equal quantity of hot water in the morning or at night, may help to "clear the tubes" and give the patient a spell of freedom from cough. In older patients the ether and ammonia mixture may be given, and in cases with bronchial spasm potassium iodide with anti spasmodics, such as stramonium, lobelia, belladonna or grindelia, may be of great value. Various antiseptic drugs, such as turpentine min 10, terebene min 5 to 10, creosote min 3 in capsules or perles, have been recommended, and the *linctus thymi et diamorphini* B.P.C. min 60. Sedative lozenges, such as compound liquorice, heroin or codeine, are often useful in checking useless cough. Intercurrent attacks of acute bronchitis must be treated on the principles described under that condition and the patient kept indoors or in bed, as may be necessary. When an advanced degree of emphysema coexists the treatment appropriate to that condition should be applied. When failure of the right heart ensues the treatment must be modified suitably as described under emphysema. Cultivation of the sputum and testing the organisms for sensitivity may indicate appropriate antibiotic treatment which can ameliorate the condition and suppress some of the infecting agents. Breathing exercises often cause great improvement for both physical and psychological reasons.

CHRONIC SUPPURATIVE BRONCHITIS

Synonym—Fetid Broochitis

Ætiology.—This condition is not sharply defined and is not a specific and separate nosological entity, but it is a convenient group in which to include cases with fetid purulent sputum. In some forms of chronic bronchitis the secretion may from time to time accumulate in the bronchi and prove offensive on expectoration. In some instances this condition becomes chronic and the expectoration is fetid up to the time of death.

Pathology.—There is chronic inflammation of the bronchi, with marked peribronchial thickening. The bronchial secretion becomes purulent, and ulceration of the bronchial wall or dilatation of the lumen may occur. Post mortem the lungs are soft, and on section some broncho pneumonia areas, with œdema of the bases, may be seen. Pus of an offensive nature exudes from the cut ends of the bronchi.

Symptoms.—These resemble those found in chronic bronchitis with, in addition, the unpleasant characteristics of the sputum in which Dittich's plugs may be found. These are small yellowish bodies, with an intensely offensive odour, composed of compact secretion.

Complications and Sequelæ.—Ulceration of the bronchial walls, abscess or gangrene of the lung, and areas of broncho pneumonia may develop. As with bronchiectasis pyæmia sometimes ensues, with the formation of secondary abscesses in the brain.

Diagnosis.—The sputum is offensive in abscess and gangrene of the lung, bronchiectasis and interlobar empyema. Radiographic examination of the chest is of great value in revealing these conditions and lipiodol investigation will usually serve to distinguish between them.

Course.—The disease is progressive, but in the early stages there may be long remissions in which the sputum is not offensive although the bronchitis persists.

Prognosis.—As the disease becomes firmly established the patient's strength is gradually undermined from the absorption of toxins, and death ensues in the course of a few years, either from exhaustion, toxæmia or pyæmia.

Treatment.—An endeavour should be made to diminish the degree of the infection and the quality of the sputum. Cultivation of the sputum will show the organisms concerned and their sensitivity to various antibiotics will decide the appropriate treatment. Postural drainage is usually helpful. Apart from this, treatment is as for chronic bronchitis. The offensive odour can be partially altered or masked by creosote given by mouth or by inhalation.

CHRONIC SECONDARY BRONCHITIS

Chronic bronchitis is a common association of chronic cardiae and renal disease. Its clinical characters do not need special description. It is only necessary to emphasise, as in the acute forms, the importance of recognising that the bronchitis is not the essential condition, and that treatment must be directed especially to the primary disease.

CHRONIC BRONCHITIS FROM MECHANICAL AND CHEMICAL AGENCIES

This usually proceeds to interstitial changes in the lung, and these results may be studied more conveniently under the heading of the pneumoconioses.

CHRONIC FIBRINOUS BRONCHITIS

Acute fibrinous bronchitis has been described above. In certain cases of chronic catarrhal bronchitis a fibrinous exudate may occur from time to time, with the formation of intrabronchial casts. There is then cough and dyspnoea, which abate with the expectoration of the cast. It therefore very closely resembles acute fibrinous bronchitis, and the treatment indicated is that described above.

TUMOURS OF THE BRONCHI

Tumours arising in the bronchi may be (a) simple or (b) malignant.

(a) *Simple tumours.*—The following varieties occur: Adenoma, lipoma, myxoma, papilloma and chondroma. Any of these may lead to bronchial obstruction and, in consequence, to collapse or bronchiectasis. Adenoma is of sufficient frequency and importance to require separate description.

(b) *Malignant tumours.*—Primary carcinoma or sarcoma may originate in the bronchi. Although the majority of primary malignant tumours within the lung originate in the bronchi, either from the lining epithelium or from the cells of the mucous glands, their pathological effects and clinical manifestations are in the main pulmonary, and it is therefore more convenient to describe them as tumours in the lung (see p. 1041).

ADENOMA OF BRONCHUS

Ætiology.—Adenoma of the bronchus occurs about equally in the two sexes, with a slight bias to the female sex, and usually in adults below the age of 40.

Pathology.—The tumour is at first small and of polypoid form, as a rule, arising in a main bronchus, but not infrequently in the branch to the lower lobe. It is about twice as common on the right side as on the left. The bulbous end is generally directed towards the trachea. The surface is usually smooth and shiny, but may be

nodular. An erroneous diagnosis of carcinoma was not uncommon in the past owing to differences of staining of certain of the constituent cells and their irregular distribution in the connective tissues. Metastases, however, are unknown. An adenoma often projects through the bronchial wall, giving it a dumb-bell or cottage-loaf conformation.

Clinical Features.—Often the earliest symptom is hæmoptysis, and this may be slight or profuse, since adenomata are very vascular and bleed easily. In other cases the tumour causes bronchial obstruction with resultant cough and wheezing, proceeding later to pulmonary collapse or bronchiectasis. Dry pleurisy may be an early result of infection, and at times pleural effusion or empyema may conceal the underlying cause.

Diagnosis.—Other causes of hæmoptysis must be considered, such as pulmonary tuberculosis, mitral stenosis, dry bronchiectasis or bronchial carcinoma. Pulmonary collapse may suggest an unresolved pneumonia. In cases with pleural effusion or empyema the diagnosis is liable to be overlooked. The injection of lipiodol, or tomography, will often reveal a blocked or deformed bronchus, but the diagnosis can only be established by microscopical examination of a portion of the tumour removed through a bronchoscope.

Prognosis.—This varies with the stage at which the diagnosis is established. If the condition is recognised early, and treated before the growth has extended outwards through the bronchial wall and before bronchial obstruction and septic infection have occurred, the outlook is favourable.

Treatment.—Lobectomy, or if necessary, pneumonectomy is now the treatment generally adopted, especially if secondary bronchiectasis or fibrosis has developed. Piecemeal removal through a bronchoscope is now seldom employed owing to the risks of hæmorrhage and of local recurrence.

THE INFECTIVE GRANULOMATA

SYPHILIS.—During the secondary stage, a generalised hyperæmia of the bronchial mucous membrane may occur, giving rise to slight bronchial catarrh with the usual symptoms and signs, a condition that has been called syphilitic bronchitis. It is frequently beneficially influenced by antisiphilitic treatment. In the tertiary stage, gummata may form in or near the large bronchi. They tend rather to fibrosis and contraction than to softening and ulceration, although the latter processes may occur. Contraction may lead to bronchial stenosis, with the symptoms and signs described below, or to extensive peribronchial inflammation and bronchiectasis. If the gummata extend into the lung, as may happen in rare instances, destructive lesions with cough, expectoration and hæmorrhage may result. This condition is more fully described in the section on pulmonary syphilis (see p. 1040).

TUBERCULOSIS of the bronchi occurs as part of pulmonary tuberculosis and does not require separate description. It may lead to bronchial stenosis, pulmonary collapse and bronchiectasis.

LEPROSY.—The bronchi may be involved in this disease, with the production of cellular infiltration and even nodule formation. At first, these lesions may produce bronchitis, and they are progressive, leading to cough, expectoration, wasting and asthenia. The general clinical picture may simulate chronic pulmonary tuberculosis, from which it is distinguished by the presence of leprosy lesions elsewhere, and the absence of tubercle bacilli from the sputum.

BRONCHIAL STENOSIS AND OBSTRUCTION

Obstruction of the main bronchi or of their subdivisions within the lungs may arise from causes within the bronchi or from conditions outside them, and these

require separate consideration. It is important to emphasise the fact that in both conditions the symptoms differ according to whether the obstruction is sudden and complete, in which case collapse of the corresponding lung is the rule, or whether it is partial and more gradual, when bronchiectasis usually results. Obstruction of the smaller bronchi may result from spasm as in asthma (see p. 977) or from disease as in small-tube and capillary bronchitis (see p. 965).

(a) INTERNAL CAUSES

These are most conveniently considered in two groups—(1) Foreign bodies; (2) those due to disease or cicatrization of the bronchial walls.

(1) FOREIGN BODIES IN THE BRONCHI

These usually gain access through the larynx and trachea by inhalation. Any inhaled foreign body that is small enough to pass down the trachea may reach a main bronchus, more commonly the right, or if it is small it may pass into one of the secondary bronchi. It may at once become impacted, or be moved by cough, but unless it is expelled in this way, it is sooner or later drawn into the smallest bronchus that will receive it, and there becomes impacted.

The recorded varieties of foreign body thus reaching the bronchi are very numerous, but among the more common are pieces of bone, beads, pins, coins, ear-rings, studs, pencils, fruit stones, grains, grasses, beans, nuts, teeth and pieces of tonsil or adenoid growths after tonsillectomy. Even a living fish has been inhaled into a bronchus. Foreign bodies may reach the bronchi through a tracheotomy wound, or a gland may ulcerate into the lumen of a bronchus. Broncholiths and pneumoliths, calcareous particles originating in the bronchi and lungs respectively, may be inhaled into a bronchus instead of being expectorated.

Pathology.—The pathological changes resulting from a foreign body in a bronchus depend upon the nature of the foreign body, the duration of its stay, the size of the bronchus obstructed by it and the degree of obstruction induced. If the foreign body is smooth and comparatively little septic, and if it be removed within 24 hours or so, complete recovery after a very mild local inflammatory reaction may be expected. If, on the other hand, the foreign body is rough, or soft and laden with septic organisms, acute pneumonic processes, often septic in character, may develop very rapidly. A soft type of foreign body may swell and completely obstruct the bronchus it reaches, leading to complete collapse of the corresponding lung area, often the whole or half of the lower lobe. If the stay of any foreign body is prolonged to days, weeks, months or longer, irreparable damage almost invariably results. The forms this may take are numerous. Collapse and septic pneumonia have already been mentioned. If the obstruction is partial, septic bronchitis, with stagnation of the bronchial exudate and pus behind the obstruction, leads in turn to peribronchitis, bronchiectasis and fibroid induration of the corresponding lung area. In other cases gangrene of the lung results. Not infrequently an empyema may occur and the foreign body may be found in the empyema cavity. Suppuration round a foreign body may lead to localised intrapulmonary suppuration or abscess. Simple bronchial obstruction, uncomplicated by sepsis, may lead to bronchiectasis, owing to the resultant lowering of intrapleural pressure.

Symptoms.—During the passage of the foreign body through the larynx and trachea urgent symptoms may occur which leave no doubt as to what has happened; but this is not invariable, and the patient may not be sure whether he has inhaled or swallowed it. In any case, after a bronchus has been reached, there may be a latent period which engenders a false sense of security and leads to delay in treatment.

In most cases pain, discomfort and cough develop rapidly. The cough may lead to the expulsion of the foreign body, or may cause dyspnoea if it forces it up to the larynx. The cough soon becomes noisy, often paroxysmal, and if local septic changes are set up expectoration occurs, sometimes mucoid and copious, at others mucopurulent. Hæmoptysis is not uncommon. Pain may be absent, but is often severe. The temperature is generally normal for the first few hours, but soon rises, especially if bronchitis, pneumonia or broncho-pneumonia develop. The further symptoms are those of the reactive changes and complications which ensue.

The physical signs naturally depend upon the bronchus affected and upon the degree of obstruction. They are at first those of deficient air entry. The affected side may show less movement, and there may be some recession of the lower intercostal spaces in young people. If a large bronchus is involved and collapse results, there is some displacement of the heart to the affected side. Vocal fremitus may be diminished or absent, the percussion note impaired, and the breath-sounds and voice-sounds weak or absent over the whole or part of one lung, almost invariably the lower lobe. If the obstruction is valvular—i.e. allowing air to pass during inspiration and not during expiration—the lung behind the obstruction may become blown up and give the physical signs of localised emphysema. The presence of an obstruction in a bronchus may cause a localised wheeze or rhoncus. When bronchiectasis, empyema or other conditions develop, their characteristic signs become apparent.

Complications and Sequelæ.—These have been enumerated in describing the pathological results. Sometimes septic meningitis or cerebral abscess develops.

Diagnosis.—The history of disappearance of some article from the mouth in the act of laughing, breathing, yawning, coughing or sighing, should always arouse suspicion of an inhaled foreign body. If signs indicating bronchial obstruction are found, the diagnosis is almost certain. In every suspicious case radiographs of the chest should be taken in two different directions, in case the shadow may be merged in that of the scapula or of the ribs. The possibility of a foreign body should always be borne in mind in cases of unilateral basic bronchiectasis, especially if no obvious cause can be found. When such unilateral lung signs develop after an anæsthetic, or after operations on the mouth or naso-pharynx, the possibility of some inhaled material should always be remembered.

Course.—Spontaneous relief may occur in two ways, either by the foreign body being coughed up, as may happen within a few hours or days or after an interval of months or years, or the foreign body may track through the lungs and pleura, and be discharged in an abscess bursting through the chest wall. In both cases, if an interval of more than days occurs, irrecoverable damage may have resulted. Apart from these occurrences and from successful treatment the course is very variable. Death may occur quickly from some of the septic complications, or after a longer or shorter interval from bronchiectasis, gangrene or cerebral abscess.

Prognosis.—This is grave unless the foreign body is removed within 36 hours, owing to the various dangerous complications that may ensue. Excluding the few cases in which cure occurs by spontaneous discharge of the foreign body, about 50 per cent. of cases left untreated die within 1 or 2 years.

Treatment.—This consists in removal, if practicable, as soon as possible after the diagnosis is established. If the foreign body is in a main bronchus or one of its principal divisions it can usually be removed by means of the bronchoscope and appropriate forceps. In case of failure the question of pneumotomy may have to be considered. If this is decided on, every effort must be made to localise the foreign body by radiographic examination. If intra-pulmonary or pleural suppuration has occurred, this must be dealt with surgically, and sometimes the foreign body can be removed at the same time. The medical treatment of the cases consists in that of the various conditions resulting.

(2) OBSTRUCTION OR STENOSIS FROM DISEASE OR CICATRISATION OF THE BRONCHIAL WALL

Ætiology.—Primary bronchial new-growths, including adenoma, columnar-celled carcinoma, oat-celled tumour and squamous-celled carcinoma lead to bronchial obstruction at an early stage. These conditions produce symptoms and signs practically identical with those of new-growths in the lung (see p. 1041).

A plug of mucus or a blood clot may cause temporary obstruction of a large bronchus.

The causes of cicatrization are those leading to ulceration of the bronchial wall, with subsequent healing, such as syphilitic processes in and around the bronchi, ulceration from injury produced by a foreign body or in its removal, or by the inhalation of severe irritants. Bronchial tuberculosis and the fibroid variety of pulmonary tuberculosis may also produce it.

Pathology.—The stenosis may occur in one of the main bronchi, or in one passing to a lobe or to part of a lobe. At first partial, it may progress until the lumen is almost completely occluded at one point. The changes occurring in the lung beyond the obstruction vary with its degree. At first there is retention of secretion in the bronchi, and air may be forced past the obstruction in inspiration, but not expelled during expiration, producing emphysema, with gradual bronchial dilatation. When the obstruction is more complete the air is absorbed, the lung tissue gradually becomes fibrotic, and the bronchi dilate further.

Symptoms.—Cough, not infrequently of paroxysmal character, is an early symptom and is usually a continuation of that caused by the primary condition. It may be dry or associated with *raucoid* sputum, sometimes blood-streaked. The expectoration may cause dyspnoea, by obstructing the narrowed bronchus. If bronchiectasis develops, the sputum usually becomes fetid.

The physical signs are those of collapse of a part of the lung and are progressive. Local limitation of movement and flattening, with displacement of the heart to the affected side, may be apparent on inspection. The vocal fremitus is diminished, the percussion note, impaired at first, may progress to complete dullness when fibrosis develops. The breath-sounds are weak or even absent, and the voice-sounds diminished. In the early stages a bronchial stridor may be audible. Compensatory emphysema of the adjacent healthy lung tissue often develops.

Complications.—These are similar to those in stenosis from a foreign body, notably fibrosis and bronchiectasis.

Diagnosis.—Bronchial cicatrization must be differentiated from obstruction due to extrabronchial causes, such as pressure from new-growths, aneurysm and the other mediastinal conditions mentioned in the section below. The history, the physical signs and examination by radiography and, if necessary, by the bronchoscope may help in distinguishing. The Wassermann reaction should be investigated in every case where the stenosis is proved to be of intrabronchial origin.

Course.—Unless the primary condition causing the stenosis is one which can be arrested by treatment, the condition is progressive, and eventually the area of lung beyond the obstruction becomes permanently functionless.

Prognosis.—This varies with the cause. It is most favourable in cases due to syphilis submitted to treatment at an early stage.

Treatment.—Vigorous antisiphilic treatment should be employed in cases due to syphilis. In other cases the treatment is to relieve symptoms by appropriate measures. Cases complicated by bronchiectasis are suitable for lobectomy.

(6) EXTERNAL CAUSES

These may be subdivided into—(1) *Mediastinal conditions*, chiefly enlargement of the bronchial or mediastinal glands from tuberculosis, Hodgkin's disease or malig-

nant growth, aneurysm of the aorta, mediastinal abscess, pericardial effusion and œsophageal new-growths. (2) *Intra-pulmonary causes*, generally primary or secondary new-growths.

Symptoms.—These are practically identical with those just described, but in addition there are those of the condition causing the pressure.

Diagnosis.—This has been discussed in the previous section. The bronchoscope should not be employed where there is any suspicion of an aneurysm.

Prognosis.—This is extremely unfavourable, except in cases due to tuberculous glands and pericardial effusion, and in some cases of mediastinal suppuration.

Treatment.—This can only be palliative in the majority of cases. Useless cough may be checked by a sedative linctus of diamorphine (heroin) or morphine. Dyspnoea when due to spasm may be lessened by inhalations of creosote and spirits of chloroform, or by administration of oxygen. Pain may be relieved by aspirin or other analgesic drugs. Deep X-ray therapy is of value in some of the malignant cases and should be tried in Hodgkin's disease or lymphosarcoma.

ASTHMA

The term asthma has been loosely employed to denote any form of dyspnoea of expiratory type occurring in paroxysms. For all conditions other than that now to be described some descriptive qualification should be employed to avoid confusion.

Asthma or true spasmodic asthma is a paroxysmal affection, occurring most frequently in patients of neuropathic inheritance. It manifests itself in attacks of severe expiratory dyspnoea due to excessive vagal discharges, set-free-by-peripheral irritation, chemical agencies or cerebral influences.

Ætiology.—Probably no other disease shows such a varied and complex causation, but studies of idiosyncrasy and anaphylaxis have served to explain many of the obscurities.

Predisposing causes.—**Age.**—The first attack may occur at any age, even as early as the period of the first dentition. The majority of cases begin before the age of 25.

Sex.—Asthma is generally stated to be nearly twice as frequent in the male sex as in the female.

Heredity.—Asthma certainly runs in families. The heredity is not always direct, the nervous instability sometimes being evidenced in other generations by migraine, epilepsy or hysteria. The view that hypersensitiveness to certain proteins is inherited is now discredited, and it is believed that an unduly irritable bronchial centre is the factor transmitted by heredity.

Other diseases.—Bronchitis not infrequently leads to paroxysms in patients with asthmatic tendencies. Tuberculosis of the lung occasionally induces it, but here again it is probably in patients with the asthmatic diathesis.

Climate and locality.—Asthmatics seem very sensitive to both of these, but no general relationship can be proved, as the effects are most variable. Some patients are better in dry, others in damp, foggy climates, and in regard to locality each patient is a law to himself.

Conditions of the nose and naso-pharynx.—Nasal obstruction from swelling of the turbinates, deflection of the septum, spurs and polypi, and conditions of the naso-pharynx, such as adenoids and enlarged tonsils, undoubtedly predispose to asthma, and may also be exciting causes of the actual paroxysm.

Exciting causes.—**Chemical substances.**—The emanations from certain animals may be the determining cause. The best known of these are the horse and cat, but rabbits, hares, guinea-pigs, deer, dogs and monkeys may have a similar effect. Even human hair appears capable of discharging the paroxysm. The dust from some substances, such as corn, rice or oats, the smell of certain drugs, such as ipecacuanha,

and the scent and the pollen of grasses and flowers may act in a similar fashion, as also may articles of diet, and many drugs. It is claimed that at least 50 per cent. of asthmatics show hypersensitiveness to various protein antigens obtainable from animals, grains, bacterial bodies, foods and drugs, and over a hundred are now available for routine testing of these patients. The analogy with the causation of hay fever and paroxysmal sneezing is obvious. This group has been referred to as "allergic" asthma.

Peripheral irritation.—As already mentioned, irritation of the nose, naso-pharynx and bronchi may be asthmogenic in those of asthmatic tendency.

Gastro-intestinal disturbance.—This is well recognised as a cause, and most asthmatics find by experience the penalties of a heavy late meal and of indigestible articles of diet. It is possible that actual metabolic errors may be a factor, as in the so-called "week-end asthma", due to altered conditions of diet and exercise at this period.

Ovarian disturbance.—Asthma may occur fairly regularly about 10 days before the onset of each period. This is probably due to lack of progesterone, from a primary ovarian defect or from an insufficient production of the gonadō-tropic luteinising hormone produced in the pituitary. Satisfactory results are usually obtained by the injection of a preparation such as Synergon, 1 ml. containing 10 mg. of progesterone and 1 mg. of oestrone per ml. This may be injected every other day during the 8 days before the period is due.

Cutaneous.—Asthmatics are peculiarly liable to urticaria and eczema, although these conditions usually alternate with the asthmatic attacks.

Nervous factors.—Fatigue, emotion and nervous shock may precipitate an attack. This factor cannot be ignored, even in cases due to protein hypersensitiveness, as is shown by a well-known case in which a patient susceptible to roses developed asthma when banded an artificial rose.

Pathology.—Numerous theories have been propounded to explain the asthmatic paroxysm. Among these may be mentioned vascular turgescence of the bronchial mucous membrane, spasm of the bronchial muscle and increased secretion of the mucous glands. Spasm of the diaphragm or of the inspiratory muscles has also been suggested. That bronchial spasm plays the major part seems to have been established by the experiments of Brodie and Dixon, and this view is strongly supported by their observations on the effects of drugs on the bronchial musculature. Muscarine, pilocarpine and physostigmine produce bronchial constriction and asthmatic symptoms in animals, while atropine, byoscyamine and chloroform abolish these effects.

There can now be little doubt that the broncho-constrictor fibres of the vagus are the channel by which the impulses discharging the asthmatic paroxysm reach the bronchi, although the possibility that impulses leading to vaso-dilatation and to increased bronchial secretion are also concerned, must be admitted.

Anaphylaxis.—The important part played by extraneous proteins in the genesis of asthma and the obvious analogy between the asthmatic paroxysm and the symptoms of anaphylactic shock have suggested that in many cases, if not in all, asthma is an anaphylactic phenomenon. Evidence is accumulating in support of this view. It has been shown that the lungs of the guinea-pig killed in anaphylactic shock show extreme constriction of the bronchioles. Asthmatics are well known to show anaphylactic tendencies, and especial care in the administration of antitoxic serums is necessary with them. It is of some interest to note that the Eppinger and Hess group of vagotonics show urticaria, dermatographia, eosinophilia and liability to anaphylactic shock, all conditions which occur in asthmatics. It is tempting, therefore, to assume that the foreign protein or toxin produces the asthmatic attack by inducing vagotonicity. Further research is needed before it can be accepted that anaphylaxis accounts for all cases of asthma, but it is almost certainly an important factor in many.

Symptoms.—The asthmatic paroxysm most commonly commences about 2 a.m. or later, but it may sometimes develop in the daytime. There are often preliminary indications some hours beforehand, constituting the "asthmatic aura". These

include restlessness, irritability, mental exaltation, less frequently depression, itching of the nose or chin, flatulence or polyuria. Some attacks are ushered in by coryza. Such warnings are not constant, and the sufferer usually wakes from sleep with a feeling of suffocation. In early attacks great restlessness, anxiety and alarm occur. The difficulty in breathing and the sense of suffocation increase, the patient sits up in bed, or gets up to throw open the window, and fixes his arms to bring into action all possible muscles of respiration. Respiration, although laboured and difficult, is often slow, inspiration being short while expiration is greatly prolonged. Both are accompanied by loud wheezing sounds, audible at a distance from the chest. The patient appears pale, but the lips are dusky and the expression is anxious and distressed. The jugular veins are distended and prominent. The accessory muscles of respiration are seen to be in violent action, notably the sterno-mastoids, scalenes and pectorals. The skin is moist and there may be marked sweating. The chest is much distended, and at each violent attempt at inspiration very little further enlargement occurs, while there is often sucking-in of the supra-clavicular and lower costal regions.

Percussion reveals marked hyper-resonance and encroachment on the cardiac and hepatic dullness. On auscultation inspiration is short and high pitched, expiration very prolonged, and both are obscured by abundant sonorous and sibilant rhonchi, and later by bubbling râles at the bases. The pulse is small, quick and sometimes irregular. There is usually marked epigastric pulsation. A differential blood count during an attack may show an eosinophilia of as much as 35 per cent. Cough does not develop until late in the paroxysm, and is quickly followed in many cases by the expectoration of small pellets, called "perles" by Laennec, and often likened to boiled sago or tapioca. These were carefully studied by Curschmann, and when examined on glass on a black background, prove to consist of a central highly refractive mucinoid coil, with masses and threads of mucin wrapped spirally around it. Microscopically leucocytes, mostly eosinophils, may be seen entangled in the mucus. The sputum frequently contains Charcot-Leyden crystals, which are now accepted as spermin phosphate. With the onset of expectoration the dyspnoea quickly lessens, and the attack subsides. The patient often passes a large quantity of pale urine and then may sleep until morning, awaking in apparent comfort. More frequently he appears pale, tired and anxious.

Diagnosis—This involves the differentiation from other forms of dyspnoea, particularly those of spasmodic expiratory type. The chief forms of paroxysmal expiratory dyspnoea are

1 *Bronchial asthma or spasmodic dyspnoea complicating chronic bronchitis and emphysema*—This condition is sometimes a late result of true asthma, but may occur independently. The dyspnoea is more persistent and is more definitely related to the bronchitic attacks, being therefore more common in the winter.

2 *Cordial dyspnoea or cardiac asthma*—This, like true asthma, is usually nocturnal, but the signs of failure of compensation in association with valvular or myocardial disease usually make the nature of the dyspnoea clear.

3 *Uræmic dyspnoea or renal asthma*—This is also not infrequently nocturnal and may be almost indistinguishable from true asthma. Examination of the urine, the urea and non protein nitrogen content of the blood, usually enable the distinction to be made with certainty. Cardio vascular changes with high blood pressure are frequently but not invariably present.

4 *Hay asthma* is probably only a severe form of hay fever and is to be regarded as a variety of true asthma.

5 *Pulmonary tuberculosis may be associated with asthmatic dyspnoea*—The differentiation may not be easy during the attack, but the persistence of apical signs in the interval may give a clue. It is a wise precaution to X ray the chest of all patients with asthma when first seen and at intervals if there are suspicious symptoms.

The dyspnoea of laryngeal or tracheal obstruction and of mediastinal pressure can

usually be recognised by the fact that it is chiefly of inspiratory type, and may be associated with stridor, instead of wheezing. In all cases of doubt the chest should be examined radiographically to exclude aneurysm, retrosternal goitre or new growth.

Course, Complications and Sequelæ—Such an attack may last from a few minutes to several hours, and may remit and then return. When the spasm is very severe and prolonged into hours, with little or no remission, the condition is often termed "*status asthmaticus*". The patient may be extremely ill, and death may occur unless the attack remits spontaneously or as a result of treatment. More often the attacks recur at the same time each night for a considerable period extending to weeks, and then pass off, after which the patient may enjoy a period of freedom of weeks or months. The intermissions may become shorter with successive attacks and increasing emphysema may develop. This in turn leads to secondary bronchitis, which persists together with some degree of permanent œdema of the bases. Later still the cardio vascular changes incidental to emphysema occur as sequels, namely, engorgement of the right heart, tricuspid regurgitation, venous stasis, ascites and œdema. Chronic asthmatics frequently present a characteristic appearance—Of thin build, with sallow complexion, anxious expression and nervous manner, they often have a long neck, high straight shoulders and a forward stoop. Asthma necessarily imposes limitations upon those who suffer from it at all severely, although many asthmatics lead active, useful lives in spite of their disease.

Prognosis.—When the disease starts in childhood or in early adult life it may stop spontaneously or be relieved permanently when some causal condition is discovered and treated. During a severe attack the aspect of the patient may be so alarming that a fatal issue may seem imminent, yet death rarely occurs. In chronic cases, the ultimate prognosis is made more serious by the complicating emphysema and bronchitis, and in spite of popular belief, the asthmatic has less than the normal expectation of life.

Treatment—(a) *During the attack*—The list of anti-spasmodic drugs and measures employed is a long one, and it is impossible to foretell which will be efficacious for asthmatics vary as widely in their response to drugs as they do in regard to asthmogenic causes. Drugs may be administered for this purpose by inhalation, by nasal sprays, by the mouth or by hypodermic injection. Adrenaline hydrochloride, in doses of 2 to 5 minims of a 1 in 1000 solution hypodermically, may act with dramatic efficacy if administered sufficiently early, but it should be given cautiously to elderly asthmatics. It may also be combined with pituitary extract, as in the special preparations Evamine, Pitrenalin and Kadamsyn. In status asthmaticus, the procedure suggested by Hurst may give relief. A syringe of 1 ml. capacity is filled with adrenaline solution 1 in 1000. This is slowly injected over a period of several minutes to half an hour or until the spasm relaxes. When relief has been obtained a preparation with a more prolonged action may be used such as adrenaline mucate (hyperdureic adrenalin) or adrenaline combined with chlorbutol and glycerin (adrenutol). An intramuscular injection of 0.5–1.0 ml. of one of these will help to prevent a recurrence for 6–8 hours. Ephedrine hydrochloride in tablets of gr. $\frac{1}{2}$ to $\frac{3}{4}$, has proved itself a useful substitute for adrenaline in some cases and can be given by the mouth. Pseudo-ephedrine in doses of gr. $\frac{1}{2}$ to 1 is often helpful where ephedrine fails. Adrenaline often proves helpful as a nasal spray, especially in combination with Chlorotone. Intravenous injections of 50 or 100 mg. of nicotinic acid may give relief when adrenaline fails. An oxygen tent is sometimes of great value in the treatment of status asthmaticus. Intravenous aminophylline in doses of 0.25 g. in 10 ml. of distilled water is often effective, especially when intramuscular adrenaline has failed. It may also be given in doses of 0.5 g. per rectum.

It is often advisable to move cases in status asthmaticus to hospital or nursing home. The change of surroundings and the different psychological atmosphere often relieves the condition.

Cortisone and corticotrophin are sometimes said to be most efficacious. The value of these substances in this condition is not fully established but they should be tried if relief is not given by other remedies. The recommended dose of cortisone by mouth is 300 mg. on the first day, 200 mg. on the second day, 100 mg. on the third day and thereafter 75 mg. daily.

Many expectorant and anti-spasmodic drugs have been used in treatment; potassium iodide and bicarbonate with tincture of stramonium, hyoscyamus or lobelia is sometimes found comforting. Suitable sedatives are paraldehyde, phenobarbitone or sodium amytal in moderate doses. Morphine should never be given to an asthmatic at any stage. In an early stage it will cause addiction, in an advanced stage it may and often does cause death.

(b) *Between the attacks.*—General advice.—Asthmatics should be taught to live as normal a life as is possible under the circumstances. There is usually no reason to restrict either their activities or diet, although patients who have nocturnal attacks find that heavy meals at night precipitate attacks and they may therefore find it advisable to have their main meal in the middle of the day. Attempts to find health by changing houses and occupation are not usually successful in themselves. Migrants from the towns in search of health are crossed by migrants from the country with similar intentions and the benefits derived from the change seem to be equally divided between the two groups.

It has been observed that some patients are sensitive to contact with certain allergens mostly of a protein nature, such as pollen, animal and vegetable hair, house dusts and similar substances. From this observation has risen the suggestion that nearly all cases are attributable to one or more sensitisations of this nature: that these sensitisations can often be detected by performing skin tests with a wide range of protein substances and that desensitisation can be carried out by injecting small doses of the sensitising agents and by increasing the dose until desensitisation is achieved. The theory of this treatment is an attractive one and a vast literature has grown up on the subject.

Similar importance has been given to treatment with autogenous vaccines prepared from the sputum or with stock vaccines. It is doubtful whether either of these two methods of treatment have anything more than a psychological value and while apparent improvement frequently takes place during such treatment, it is more often due to the psychological effect of an impressive treatment and the personality of the doctor than to any desensitising effect.

Attempts are made to treat patients by special diets. Children are the especial victims of this form of "therapy". There is little evidence that bronchial asthma is ever caused by the ingestion of any particular food substance, although such ingestion occasionally causes alimentary symptoms. The effect of these diets is often to make patients even more introspective than they naturally tend to be.

Exaggerated attempts are sometimes made to render allergen-free the atmosphere in which the patient lives or sleeps. Such measures condemn the patient to discomfort and disappointment. The fact that many sufferers from asthma also suffer from rhinorrhœa, have nasal polyps, deflected septa or sinus infection has led to many misguided surgical and electrical misadventures. All these treatments and many others had and have their strong adherents amongst doctors and even patients.

There is an especial difficulty in assessing the value of any special treatment in asthma since the natural history of the disease is so variable and sufferers from it are so susceptible to suggestion. In default of any specific treatment, there are general measures and advice which are helpful. The patient should be advised to try and not let his asthma dominate his life. Children should go to normal schools and play games as normally as possible. There is no need for a special diet except that patients are usually well advised not to have a heavy meal in the evening as a full stomach, when recumbent, appears to cause attacks. They should avoid dusty house-cleaning

and keep out of dusty atmospheres. If they are sensitive to horse dandruff, vegetable pollens or other single substances they should avoid them, and the patients usually recognise these substances without having to have skin tests to identify them. They should receive instruction in the use of ephedrine, or if this is ineffective or loses its effect, adrenaline by injection or by inhalation. Knowledge that one has the means of relief at the outset of an attack often means that the attack will not develop. Many of the proprietary inhalants and patent inhalers are quite effective if used early enough. Most patients benefit from instruction in expiratory breathing exercises which may, of course, act by suggestion but which also have a manifest effect on the mobility of the chest and the respiratory excursion.

Advice to change a patient's home or occupation should not be given lightly. Such steps are rarely effective unless there is some very real and obvious domestic or occupational hazard.

Cortisone and corticotrophin are not usually required in the treatment of chronic asthma but they have been used with great benefit at times when all other measures have failed. Cortisone may be administered orally in such cases in the form of cortisone acetate tablets. An initial dose of 200 mg. followed by 100 mg. daily for 2 or 3 days may be necessary at the commencement of treatment. Thereafter symptoms can usually be controlled by quite small doses; 25 mg. to 50 mg. at bedtime usually being sufficient.

BRONCHIECTASIS

Definition.—Bronchiectasis is a condition of permanent dilatation of one or more bronchi. When it occurs in the finer divisions it is sometimes described as bronchiolectasis.

Ætiology.—Bronchiectasis is invariably secondary, and may result from disease of the bronchi, the lung parenchyma or the pleura. Even the rare congenital cases are probably consequent on malformation, atelectasis or intra-uterine disease.

1. The bronchial conditions which may progress to dilatation are bronchitis, and any affection leading to partial bronchial obstruction, such as plugs of mucus, an inhaled foreign body, a tumour (simple or malignant), stenosis from cicatrization and external pressure from new-growth or aneurysm, or enlarged bronchial glands from any cause but more especially from tuberculosis. Localised pulmonary collapse thus induced seems to be the commonest antecedent condition. In children, measles and whooping-cough are not uncommon causes, especially when they follow one another in rapid succession, although either alone, if severe, may lead to it.

2. Conditions of the lung parenchyma which may cause bronchiectasis are unresolved pneumonia, broncho-pneumonia, collapse, syphilis and tuberculosis. Syphilis is rare and usually acts by leading to bronchial obstruction or stenosis. Fibroid tuberculosis is a common cause, but the clinical manifestations are, as a rule, masked by the primary condition. The pulmonary complications of influenza are not infrequently followed by bronchiectasis. A diffuse type of bronchiectasis is sometimes found in long-standing cases of asthma.

3. The pleural conditions which are followed by bronchiectasis are those which lead to pleural adhesion and those which are associated with pulmonary fibrosis, notably chronic pleural thickening, or empyema leading to prolonged or permanent collapse of the lung.

In a lesion with such diverse antecedents the age relations are necessarily indefinite. It may occur at any age, but is commonest in the third and fourth decades. It frequently commences in childhood, although the characteristic clinical manifestations may not develop until adult life.

Sex.—In most recorded statistics there is a striking preponderance in the male.

Pathology.—Four factors in the pathogenesis of bronchial dilatation have to be

considered. (1) The most important is the localised collapse which leads to secondary bronchial dilatation. (2) Weakening of the bronchial walls. Most of the conditions preceding bronchiectasis tend to induce severe bronchitis and peribronchitis, and thus render the walls more yielding. Where stagnation of secretion occurs, septic and putrefactive organisms develop, producing tryptic ferments which may act injuriously upon the lining membrane. (3) Increased pressure on the walls thus weakened is the determining factor. This is generally expiratory in origin and due to the strain of cough. The actual pressure of secretion accumulating behind an obstruction may promote yielding of the bronchial walls. In cases of bronchiectasis following on collapse of the lung the force of inspiration has been regarded as contributory, but this is doubtful and in any case is less important than the expiratory strain of cough. (4) The fourth possibility is the traction exerted upon the walls of the bronchi by contracting connective tissue in the surrounding fibroid lung. This obviously postulates the existence of pleural adhesion, which is not invariably present. While this must be admitted as a possible contributory factor, its importance is certainly less than that of the preceding ones.

Congenital bronchiectasis is a pathological rarity and may be confused with congenital cystic disease of the lung (see p. 1044). It is usually unilateral, and the bronchi involved are of small size, although in some cases the lung may show a large central cavity, with smaller spaces around it. Bronchiolectasis is also more of pathological than of clinical interest. It occurs chiefly in children, as the result of acute broncho-pneumonic processes. It is said sometimes to follow influenza and possibly tuberculosis. The lung has a peculiar spongy appearance, to which the name "honey-comb" has been applied.

Bronchiectasis of the larger tubes may be either cylindrical or saccular. In the former condition several of the bronchi are more or less uniformly dilated, and when opened out they appear like the fingers of a glove. Sometimes the dilatations are fusiform, at others they show a beaded arrangement, described as moniliform. These forms of dilatation are usually associated with emphysema and chronic bronchitis. Saccular bronchiectasis is generally localised and may be found in any part of the lung, but is most common in the lower lobes and near the base. This is partly due to the fact that the antecedent processes fall with special stress on the bases of the lung, and partly to the influence of gravity in leading to retention of secretions in these parts. Although it may be unilateral in origin, it often spreads and may involve both bases or even all the lobes. There may be one large irregular cavity, or a series of smaller globular dilatations involving the whole or part of the walls of one or more bronchi. The cavities are usually filled with the fetid secretion, to be described under expectoration. When this is washed away the walls are found to be thin, smooth and formed of thinned-out mucous membrane. In places this may have ulcerated, owing to the tryptic action of the secretion, and the lung tissue is thus exposed. An abscess may then form, and an aneurysm sometimes develops, as in a tuberculous cavity. The openings of the smaller bronchi, derived from the dilated bronchus, can often be recognised in its walls. In doubtful cases the histological demonstration of cartilage and muscle in the walls establishes the bronchial origin of a cavity. The surrounding lung tissue is usually airless and fibroid, and sometimes is almost of leathery consistence. Occasionally, however, it is emphysematous, congested or pneumonic. In the great majority of cases there is a dense pleural adhesion over the area of lung involved.

Other morbid conditions found post mortem include lardaceous disease, gangrene of the lung, empyema, pyo-pneumothorax, suppurative pericarditis and cerebral or spinal cord abscess. Owing to the obstruction of the pulmonary circulation which may result, engorgement and dilatation of the right side of the heart, tricuspid regurgitation and the results of systemic venous stasis are often found.

Symptoms.—The onset is usually insidious, the symptoms developing during

and keep out of dusty atmospheres. If they are sensitive to horse dandruff, vegetable pollens or other single substances they should avoid them, and the patients usually recognise these substances without having to have skin tests to identify them. They should receive instruction in the use of ephedrine, or if this is ineffective or loses its effect, adrenaline by injection or by inhalation. Knowledge that one has the means of relief at the outset of an attack often means that the attack will not develop. Many of the proprietary inhalants and patent inhalers are quite effective if used early enough. Most patients benefit from instruction in expiratory breathing exercises which may, of course, act by suggestion but which also have a manifest effect on the mobility of the chest and the respiratory excursion.

Advice to change a patient's home or occupation should not be given lightly. Such steps are rarely effective unless there is some very real and obvious domestic or occupational hazard.

Cortisone and corticotrophin are not usually required in the treatment of chronic asthma but they have been used with great benefit at times when all other measures have failed. Cortisone may be administered orally in such cases in the form of cortisone acetate tablets. An initial dose of 200 mg. followed by 100 mg. daily for 2 or 3 days may be necessary at the commencement of treatment. BRONCHIECTASIS

Definition.—Bronchiectasis is a condition of permanent dilatation of one or more bronchi. When it occurs in the finer divisions it is sometimes described as bronchiolectasis.

Ætiology.—Bronchiectasis is invariably secondary, and may result from disease of the bronchi, the lung parenchyma or the pleura. Even the rare congenital cases are probably consequent on malformation, atelectasis or intra-uterine disease.

1. The bronchial conditions which may progress to dilatation are bronchitis, and any affection leading to partial bronchial obstruction, such as plugs of mucus, an inhaled foreign body, a tumour (simple or malignant), stenosis from cicatrization and external pressure from new-growth or aneurysm, or enlarged bronchial glands from any cause but more especially from tuberculosis. Localised pulmonary collapse thus induced seems to be the commonest antecedent condition. In children, measles and whooping-cough are not uncommon causes, especially when they follow one another in rapid succession, although either alone, if severe, may lead to it.

2. Conditions of the lung parenchyma which may cause bronchiectasis are unresolved pneumonia, broncho-pneumonia, collapse, syphilis and tuberculosis. Syphilis is rare and usually acts by leading to bronchial obstruction or stenosis. Fibroid tuberculosis is a common cause, but the clinical manifestations are, as a rule, masked by the primary condition. The pulmonary complications of influenza are not infrequently followed by bronchiectasis. A diffuse type of bronchiectasis is sometimes found in long-standing cases of asthma.

3. The pleural conditions which are followed by bronchiectasis are those which lead to pleural adhesion and those which are associated with pulmonary fibrosis, notably chronic pleural thickening, or empyema leading to prolonged or permanent collapse of the lung.

In a lesion with such diverse antecedents the age relations are necessarily indefinite. It may occur at any age, but is commonest in the third and fourth decades. It frequently commences in childhood, although the characteristic clinical manifestations may not develop until adult life.

Sex.—In most recorded statistics there is a striking preponderance in the male.

Pathology.—Four factors in the pathogenesis of bronchial dilatation have to be

considered. (1) The most important is the localised collapse which leads to secondary bronchial dilatation. (2) Weakening of the bronchial walls. Most of the conditions preceding bronchiectasis tend to induce severe bronchitis and peribronchitis, and thus render the walls more yielding. Where stagnation of secretion occurs, septic and putrefactive organisms develop, producing tryptic ferments which may act injuriously upon the lining membrane. (3) Increased pressure on the walls thus weakened is the determining factor. This is generally expiratory in origin and due to the strain of cough. The actual pressure of secretion accumulating behind an obstruction may promote yielding of the bronchial walls. In cases of bronchiectasis following on collapse of the lung the force of inspiration has been regarded as contributory, but this is doubtful and in any case is less important than the expiratory strain of cough. (4) The fourth possibility is the traction exerted upon the walls of the bronchi by contracting connective tissue in the surrounding fibroid lung. This obviously postulates the existence of pleural adhesion, which is not invariably present. While this must be admitted as a possible contributory factor, its importance is certainly less than that of the preceding ones.

Congenital bronchiectasis is a pathological rarity and may be confused with congenital cystic disease of the lung (see p. 1044). It is usually unilateral, and the bronchi involved are of small size, although in some cases the lung may show a large central cavity, with smaller spaces around it. Bronchiolectasis is also more of pathological than of clinical interest. It occurs chiefly in children, as the result of acute broncho-pneumonic processes. It is said sometimes to follow influenza and possibly tuberculosis. The lung has a peculiar spongy appearance, to which the name "honey-comb" has been applied.

Bronchiectasis of the larger tubes may be either cylindrical or saccular. In the former condition several of the bronchi are more or less uniformly dilated, and when opened out they appear like the fingers of a glove. Sometimes the dilatations are fusiform, at others they show a beaded arrangement, described as moniliform. These forms of dilatation are usually associated with emphysema and chronic bronchitis. Saccular bronchiectasis is generally localised and may be found in any part of the lung, but is most common in the lower lobes and near the base. This is partly due to the fact that the antecedent processes fall with special stress on the bases of the lung, and partly to the influence of gravity in leading to retention of secretions in these parts. Although it may be unilateral in origin, it often spreads and may involve both bases or even all the lobes. There may be one large irregular cavity, or a series of smaller globular dilatations involving the whole or part of the walls of one or more bronchi. The cavities are usually filled with the fetid secretion, to be described under expectoration. When this is washed away the walls are found to be thin, smooth and formed of thinned-out mucous membrane. In places this may have ulcerated, owing to the tryptic action of the secretion, and the lung tissue is thus exposed. An abscess may then form, and an aneurysm sometimes develops, as in a tuberculous cavity. The openings of the smaller bronchi, derived from the dilated bronchus, can often be recognised in its walls. In doubtful cases the histological demonstration of cartilage and muscle in the walls establishes the bronchial origin of a cavity. The surrounding lung tissue is usually airless and fibroid, and sometimes is almost of leathery consistence. Occasionally, however, it is emphysematous, congested or pneumonic. In the great majority of cases there is a dense pleural adhesion over the area of lung involved.

Other morbid conditions found post mortem include lardaceous disease, gangrene of the lung, empyema, pyo-pneumothorax, suppurative pericarditis and cerebral or spinal cord abscess. Owing to the obstruction of the pulmonary circulation which may result, engorgement and dilatation of the right side of the heart, tricuspid regurgitation and the results of systemic venous stasis are often found.

Symptoms.—The onset is usually insidious, the symptoms developing during

the course, or as a sequel, of one of the acute or chronic affections mentioned above. In some few cases, however, they develop rapidly in patients previously in good health. This is particularly the case where bronchiectasis results from an inhaled foreign body or after general anæsthesia, and a rapid onset should lead to the suspicion of this. The cough in well-developed cases is somewhat characteristic and occurs in paroxysms. These are frequently induced by change of posture—for example, bending forward or lying down. They occur with special frequency on rising, and are usually associated with the expectoration of large quantities of sputum, due to the overflow of the secretion, accumulated in the cavities during the night, into a sensitive or relatively healthy bronchus, which excites cough reflexly. They also occur on retiring to bed and at long intervals during the day. The sputum frequently amounts to as much as 20 or 30 oz. in the 24 hours. It is generally extremely fetid, although in the earlier stages this is not invariable. The patient's breath is often also malodorous, and the stench may pervade the room or even the house in which he lives, although it is not persistent. The patient is himself much distressed by the unpleasant character of the sputum, of which he is, as a rule, acutely conscious. On standing in a glass vessel it can be seen to settle into three layers—a surface scum of light frothy mucus, an intermediate stratum of thin, turbid, greenish fluid, and a deep layer of brownish colour consisting of muco-pus, bacteria, anaerobes, spirochaetes and putrefactive products, including foul-smelling organic acids. Fetid yellow bodies called Dittrich's plugs can usually be found in the deep layer. Elastic tissue is only present when erosion of the wall has occurred. Hæmoptysis is not infrequent, and may occasionally be fatal. It may be the first and only symptom in some cases, which are referred to as dry or silent bronchiectasis. Dyspnoea is not, as a rule, apparent unless the condition is widespread, or unless the pulmonary or cardiac complications are present. The general condition of the patient is at first but little affected, and there may be no fever for long periods. As the disease progresses, lassitude, anorexia and some wasting slowly develop, while bouts of fever occur, due to retained secretions or to some complication.

Physical signs vary with the extent and degree of dilatation, and also with the amount of secretion present. In the early stages there is at most slight dullness at one base, with diminished air entry, peculiar sticky, "leathery" râles, and diminished vocal resonance. When bronchiectasis is well developed the signs are almost characteristic. The patient may appear well nourished and of good colour, although on cold days, especially in children, duskiness or cyanosis is often noticeable. There is well-marked clubbing of the fingers, generally of drum-stick character, and pulmonary osteo-arthropathy, involving many joints, sometimes develops. There may be localised flattening or retraction of the chest wall over the affected area, with diminished movement, and the heart is drawn over to this side. The remaining signs vary with the state of the cavity. If this is full, there is diminished vocal fremitus, dullness and weak or absent breath-sounds and voice-sounds. If the cavity is empty or partly empty, the vocal fremitus is increased, the percussion note is boxy or dull, while the breath-sounds are bronchial or cavernous. Adventitious sounds are then generally audible, the most characteristic being sharp metallic or "leathery" râles. Bronchophony and pectoriloquy are marked, and occasionally the "veiled puff" of Skoda can be heard. Signs of bronchitis are often apparent in the adjacent lung tissues; compensatory emphysema may be demonstrable in the unaffected parts of the lung, and on the opposite side. Radiographic examination before and after the injection of lipiodol serves to define the extent of the disease and the degree of fibrosis. Tomography may also be useful.

Complications and Sequelæ.—The chief pulmonary complications are septic broncho-pneumonia, gangrene and abscess. The pleura may become involved, giving rise to dry pleurisy, which sometimes progresses to empyema and rarely to pyopneumothorax, while in other cases pleural adhesion and contraction result. Septic

pericarditis may develop and prove fatal. Septicæmia and pyæmia sometimes occur as terminal results. Cerebral abscess constitutes a serious and somewhat common complication in heavily infected cases, and may be found in the frontal, parietal or temporal regions, or suppuration may occur in the cerebellum or cord. Occasionally multiple abscesses form. Lardaceous disease sometimes develops, especially in the liver, kidneys and intestines. Multiple infective arthritis is an occasional complication.

Diagnosis—In well developed basic cases this is, as a rule, easy. The history of cough, influenced by posture and associated with copious sputum, is suggestive, especially when variable physical signs are observed. The development of the characteristic sputum with these signs renders the diagnosis almost certain, and the radiograph usually serves to confirm. Radiological investigation after an intra-tracheal injection of 10 to 20 ml. of lipiodol, through the crico-thyroid membrane or between two rings of the trachea, under local anaesthesia, or with care directly between the vocal cords, has greatly facilitated the diagnosis of bronchiectasis. Franklin has recommended the nasal route for the introduction of the lipiodol. One nostril, the oro-pharynx and the larynx are anaesthetised, then a gum elastic catheter is passed along the floor of the nose into the larynx. Procaine or other local anaesthetic is injected down the catheter and the lipiodol follows. Tilting and turning the patient in appropriate directions is done in order that the lipiodol should pass into the diseased portions of the bronchial tree. The injection should be carried out in the radiographic room and the patient instructed to restrain cough if possible until the films have been taken. The pictures obtained are strikingly characteristic and of great value. In cases with less characteristic symptoms and signs the distinction has to be made from chronic bronchitis, especially the fetid variety, pulmonary tuberculosis gangrene or abscess of the lung, and fetid empyema. The distinction from chronic bronchitis may be difficult, especially in the early stages when the sputum is not fetid, but the paroxysmal cough, the copious expectoration with signs including bronchial breathing and sticky râles at the base, may be strongly suggestive. In fetid bronchitis the fetid sputum is not constant and the cough and sputum may occur only during exacerbations of the bronchitis. Pulmonary tuberculosis may give rise to difficulty, particularly in cases of apical bronchiectasis. Repeated examinations for tubercle bacilli and also for elastic tissue in the sputum should be made. The history, the mode of spread and radiographic examination may all assist. It should be remembered that the two conditions may coexist and this may be suspected in some cases of fibroid tuberculosis with basic excavation. Abscess and gangrene of the lung have a more acute onset and course, but the chronic cavities left by these conditions may give rise to difficulty. In such cases the history may be an important aid in diagnosis. In fetid empyema rupturing through the lung, particularly when of interlobar origin, the patient is generally acutely ill, there may be a history of pleurisy at the onset and possibly some evidence of mediastinal pressure or cardiac displacement. The rare condition of congenital cystic disease of the lung may give rise to some difficulty (see p. 1044).

Course—This depends on the extent of the bronchial involvement and the degree of infection. Probably only a small percentage of cases of bronchiectasis are clinically diagnosed. Those that are, are usually both extensive and heavily infected. Without treatment the condition tends to be progressive and leads to complications, many of which are lethal.

Prognosis—Surgeons and physicians tend to have different ideas about the prognosis of bronchiectasis. The former are often of the opinion that without surgical treatment the prognosis is hopeless and the expectation of life short. The latter are not quite so pessimistic. The reason for this difference of opinion is that the surgeon tends to see a rather special selection of the worst cases, the physicians see these and also many cases which are little or at all progressive.

Given morbid anatomical bronchiectasis the prognosis is uncertain, but severely infected cases, with much foul sputum, repeated hæmoptyses and pyrexial episodes, are progressive with a short expectation of life failing adequate treatment, but there are exceptions even to this.

Treatment.—The medical treatment of bronchiectasis consists of efforts to secure efficient emptying and drainage of the affected part of the lung, to lessen or control the infective processes occurring in the lung and to promote the general health and well-being of the patient. Bronchograms of the affected lobe or lobes indicate the desirable position for evacuation of the lung. In bronchiectasis of the lower lobes the patient either bends over or his feet are raised so that the bifurcation of the trachea is below the level of the affected lung. If the anterior bronchi are affected, he lies on his back and if the posterior bronchi are affected he lies on his face. He should also be tilted on his side so that the affected side is uppermost. The best position for drainage can usually be found by a process of trial and error. The longer the appropriate position is maintained the more effective the result. In any case it should be maintained for not less than 30 minutes at a time. The initial instruction is best given by a qualified masseuse and the treatment must be maintained for life if the lobe is not going to be removed surgically. The Nelson bed, hinged in the middle, is helpful in maintaining the correct posture long enough for drainage to occur.

The sputum should be cultivated and the organisms identified and their drug sensitivity tested. The quantity and degree of infection can be altered by the appropriate use of antibiotic preparations, although the development of drug resistance reduces their effectiveness. They are especially valuable during pyrexial periods of exacerbation of infection due to defective drainage. Penicillin inhalations have some limited effect but no drug is really effective if the drainage from the affected bronchi is poor.

Creosote given by inhalation or in capsules of 3 minims was much used in the past and it has value in helping to disguise the factor of the breath, which is one of the most distressing features of these cases. Bronchoscopic aspirations have been found effective in some cases, especially those where bronchostenosis or bronchial œdema prevents effective drainage.

The possibility of treatment by surgical segmental resection, by lobectomy or pneumonectomy should be considered. Surgeons have no doubt about the value of prophylactic surgery and may advise resection for anatomical bronchiectasis without symptoms. Many physicians are not so convinced of the necessity of these resections. Differences of opinion represent a different idea of the prognosis. There is unanimity about the desirability of resection for the infected cases with much sputum daily, with repeated pulmonary hæmorrhages or with a history of recurrent attacks of "pneumonia" or pyrexial episodes. Thoracic surgery has had no more dramatic successes than in these cases. Unfortunately in many of the worst cases the disease is too extensive for removal to be possible. In these cases medical treatment palliates and prolongs life.

DISEASES OF THE LUNGS

HYPERÆMIA AND ŒDEMA

Hyperæmia of the lungs may be either active or passive. In the former there is an increased supply of arterial blood through the pulmonary and bronchial arterioles. In passive hyperæmia there is engorgement of the pulmonary venous radicles and capillaries. With both forms there is frequently œdema, due to the exudation of serous fluid into the lung alveoli. The term "congestion" is sometimes employed as an alternative to hyperæmia, but owing to its erroneous popular use it is best avoided.

(a) ACTIVE HYPERÆMIA

Ætiology.—This may occur in association with any acute inflammatory process affecting the bronchi, lungs or pleura. It sometimes results from the inhalation of pulmonary or bronchial irritants, such as poisonous gases or heated air. Severe muscular exertion and exposure to extreme cold are described as causes, but the former at least is doubtful. An important variety is that known as collateral or fluxionary hyperæmia, which occurs when there is obstruction to the circulation in the whole or part of one lung, from conditions such as a large or rapidly developing pleural effusion, an extensive and spreading pneumonia, or in association with pneumothorax. This may develop in the sound lung, or in the unaffected parts of that diseased. A primary form of acute hyperæmia, the "maladie de Woillez", has been recognised by French authors, but this is generally regarded as a mild or abortive pneumonia.

The clinical manifestations of acute hyperæmia are merged in those of the processes with which it is associated, and therefore do not need separate description.

(b) PASSIVE HYPERÆMIA

Ætiology.—Passive hyperæmia may be produced by conditions impeding the venous return from the lungs. The commonest causes of impeded return are left-sided heart lesions causing overfilling of, and increased pressure in, the left auricle. In mitral stenosis it may occur early and sometimes almost acutely, but aortic and myocardial lesions also lead to it, when the left ventricle fails and the mitral valve yields. Direct obstruction of the pulmonary veins sometimes results from external pressure by aneurysm, mediastinal tumour or enlarged bronchial glands, or from obstruction of the lumen by thrombosis.

Passive hyperæmia is obviously in the main dependent on mechanical factors; it is not surprising, therefore, that gravity seems to play a part in the localisation of its effects, which are usually most marked in the bases or most dependent parts of the lungs. In bedridden, enfeebled or old patients, particularly if myocardial weakness or degeneration coexists, this factor becomes of great importance. Not infrequently some degree of œdema of the bases develops, and the condition is then called hypostatic congestion. If such an area becomes infected the resulting process is known as hypostatic pneumonia. Basal hyperæmia and œdema of the hypostatic type also result from toxæmia due to diseases such as enteric fever, from poisoning by drugs such as morphine, and as a terminal event in many cerebral lesions causing increased intracranial pressure.

Pathology.—The pulmonary veins and capillaries are engorged, with the result that the lung is darker in colour and heavier, while the alveolar walls and septa are swollen. If the condition persists for some time, pigment derived from the hæmoglobin of red corpuscles escaping by diapedesis is deposited in the epithelium of the

alveoli and in the fibroblasts in the inter alveolar septa. In long standing cases the lung is firmer than normal and brownish red in colour, a condition described as brown induration. If any degree of œdema is present, serous fluid is found in the alveoli on post mortem examination, and on section of the lung frothy serous fluid exudes which may contain some of the pigmented alveolar cells, constituting what are called "cardiac cells". Although congested and œdematous lung is heavier than normal, it usually floats in water.

Symptoms—In slight degrees of hyperæmia these may be absent or negligible. In more advanced cases they are those resulting from the impeded circulation through the lungs and the deficient aeration which this entails. Dyspœnia is the most prominent symptom and it is generally a measure of the degree of hyperæmia. It is markedly increased by exertion of any kind, and in extreme degrees it is distressing and eventually alarming. It may be inspiratory or expiratory in type, and in the latter case it is sometimes described as cardiac asthma. In severe cases there is usually orthopœnia. Cough is almost invariably present, and there is usually some expectoration of frothy fluid, which may be blood stained. The pigmented cells referred to above as "cardiac cells" may be found in it. Cyanosis is common and indicates the degree of anoxæmia. This may be associated with distension of the jugular veins and there is often obvious distress. As in other forms of cyanosis there is usually some increase in the number of red corpuscles. The vocal fremitus at the bases may be diminished, the percussion note impaired, the breath sounds weak and accompanied by rhonchi, crepitations or bubbling râles, although these signs are for the most part due to the associated œdema. In addition, the signs of the primary condition in the heart will be apparent.

Complications—Pulmonary œdema and infarction are the chief complications.

Diagnosis—This condition has to be distinguished from (1) chronic bronchitis, in which case there may be some rise of temperature and the physical signs are more variable and more disseminated, (2) infarction, in which pain and hæmoptysis of sudden onset are the rule.

Course—If the venous engorgement cannot be removed it tends to become progressively worse, whereas when it results from temporary cardiac embarrassment recovery is usually complete as soon as the heart function is restored.

Prognosis—This is so entirely dependent upon the nature and degree of the condition responsible for the engorgement that no general rule can be formulated.

Treatment—The treatment is that of heart failure, with digitalis, salt restriction and mercurial diuretics. In elderly patients or those likely to be confined to bed for long periods, attention should be directed to the decubitus. This should be changed frequently, and if possible the patient should be permitted to sit up or to get into a chair, and encouraged to take a few deep breaths several times during the day.

(c) ACUTE OR HYPERACUTE PULMONARY ŒDEMA

In this condition flooding of the alveoli with the serous exudate from the pulmonary capillaries occurs with great rapidity.

Ætiology—The most important cause of pulmonary œdema is left heart failure whether from hypertension disease of the aortic or mitral valves or coronary thrombosis. Pulmonary œdema may also occur in acute cor pulmonale from pulmonary infarction. It may complicate exposure to lung irritant gases, or disease of the nervous system, such as tumour, vascular accident or trauma or intravenous transfusion, or disturbance of the fluid balance in treatment with deoxycortone acetate (DOCA) cortisone or stilbestrol. Sometimes paracentesis of large effusions is followed by pulmonary œdema.

Pathology—The alveoli are found to be flooded with a thin serous exudate. The lungs are heavier than normal, sodden, and on squeezing exude large quantities

of greyish-yellow or pinkish fluid. Frothy fluid of similar character is found in the bronchi and even in the trachea and naso-pharynx in hyperacute cases.

Symptoms.—The onset is sudden, and generally occurs when the patient is lying down, hence being most frequently observed at night. The patient awakes with intense dyspnoea, and a sense of suffocation, then frequently rolls or rushes about in the endeavour to breathe, even clutching at the throat. Cyanosis is present, and the aspect is one of anxiety and alarm. Frothy fluid, often pink in colour, may soon stream from mouth and nose, or be brought up in great gulps. The chest movements are hurried, and the accessory respiratory muscles are in violent action. Vocal fremitus is diminished over the lower lobes. The percussion note soon becomes impaired over the lungs, commencing at the bases. The breath-sounds are at first vesicular or harsh with prolonged expiration, then become faint and may be obscured by bubbling râles or crepitations, audible all over the chest. Voice conduction is diminished.

Complications and Sequelæ.—Owing to its acute and rapid course, complications do not occur. Bronchitis may result as a sequela.

Diagnosis.—The affection is usually so characteristic that the diagnosis is obvious. In the more protracted cases the dyspnoea and the physical signs are not unlike those of acute suppurative bronchitis or suffocative catarrh and broncho-pneumonia; but in both of these there is some degree of fever and the expectoration is less copious, and when it occurs is usually of purulent or muco-purulent character. The nocturnal onset of œdema may suggest asthma; but the physical signs and the late and scanty expectoration in the latter suffice to distinguish it.

Course.—The malady usually lasts only minutes or hours. Unless it remits, or treatment affords relief, the patient rapidly becomes unconscious and death follows, the heart continuing to beat after respirations have ceased.

Prognosis.—The prognosis is always very grave; but prompt treatment has saved some cases. Death may occur in less than 10 minutes, or be delayed for 24 or 48 hours.

Treatment.—The most successful treatment is the immediate subcutaneous injection of morphine gr. $\frac{1}{4}$. Good results have also followed the injection of atropine sulphate, gr. $\frac{1}{100}$ to $\frac{1}{50}$ hypodermically. Intravenous injection of aminophylline has been recommended. The dose is 0.25 g. in 10 ml. of distilled water. Oxygen inhalation by nasal catheter or the B.L.B. mask or oxygen tent is of value in some cases; others derive no benefit from it. Prompt venesection has been recommended.

(d) CHRONIC PULMONARY ŒDEMA

This is usually the sequel of chronic passive hyperæmia, and the causes and symptoms are those of that condition. It may also occur in chronic renal disease. In marked degrees of œdema, however, the signs may closely simulate those of pleural effusion, save for the displacement of the cardiac impulse. It is important to remember that some degree of hydrothorax may occur as a complication, and increase the difficulty in diagnosis.

INFARCTION OF THE LUNGS

Infarction of the lungs or "pulmonary apoplexy" results when a branch of the pulmonary artery becomes occluded by embolism or thrombosis.

Ætiology.—*Embolic forms.*—The obstructing plug may originate in any part of the systemic venous system, in the right side of the heart or on its valves or in the pulmonary artery itself. The commonest peripheral cause of embolism is detachment of a thrombus in cases of thrombo-phlebitis. This may occur in the veins of

the lower extremity, or in those of the uterus after childbirth. Thrombosis with embolic detachment may also develop in prolonged or wasting diseases, such as enteric fever, tuberculosis and cancer; in acute processes, such as influenza, septicæmia and pyæmia; and in localised septic lesions, such as otitis. Pulmonary embolism is not infrequently observed after abdominal or pelvic operations, and after the radical cure of hernia or hæmorrhoids.

Intracardiac thrombi from the right auricle or ventricle, becoming detached, lead to embolism, and this occurs especially in cases of right-sided heart failure secondary to left-sided valve lesions. Vegetations forming on the tricuspid or pulmonary valves in septic endocarditis on detachment produce pulmonary infarction. Rarer causes are fat embolism after injury to bone or to a fatty liver, the entry of pieces of new-growth or hydatid daughter-cysts into systemic veins, and even air embolism, occurring sometimes as a complication of pneumoperitoneum. It may also occur during blood transfusion if the pressure in the bottle is raised unduly by a Higginson's syringe while the filter is partially blocked. Air embolism has followed insufflation of the vagina with silver picrate powder in the treatment of vaginitis and trichomonas infections.

Thrombotic forms.—Thrombosis occurs as a secondary process around pulmonary emboli; but it is probable that some cases of infarction are due to a primary thrombosis. This condition may be produced by some acute or chronic pulmonary disease, such as gangrene, tuberculosis and fibrosis, and by atheroma of the pulmonary artery. Any process leading to chronic venous hyperæmia may also cause it. A rare cause is thrombo-phlebitis migrans.

Pathology.—Although the pulmonary arteries are not strictly speaking end arteries, since there is some degree of anastomosis between them and the bronchial arterioles, yet the result of their obstruction is to produce infarcts comparable with those in other organs. The origin of the blood in the obstructed area has been much discussed. Cohnheim regarded it as the result of regurgitation from the veins, a view subsequently disproved, since the infarct is hæmorrhagic even when the veins are also obstructed. It is now regarded as due to influx from the anastomosing bronchial capillaries into the pulmonary capillaries, and the escape of this blood from the latter owing to their altered nutrition. It is generally accepted that embolism is much more common than thrombosis. If a large embolus has caused sudden death, it will be found arrested at the bifurcation of a large branch of the pulmonary artery, or even in one of the main divisions of that vessel. In such cases there has not been time for pulmonary changes to occur, and the chief post-mortem condition found is engorgement of the right side of the heart.

In post-mortem examination of cases where smaller emboli have led to infarction, the infarcts are usually found in the lower lobes, more commonly in the right lung. They extend to the surface in the majority of cases, and can be seen before section as slightly raised, dark-red areas, with the overlying pleura a little roughened from inflammatory exudate. They feel hard and firm, and on section are typically wedge-shaped, with the base on the surface and the apex centrally placed. In the rare deep-seated infarcts a spheroidal form is the rule. When recent, an infarct is dark red in colour, and suggests hæmorrhage with clot formation, hence the term "pulmonary apoplexy". In some cases infarcts have a purplish blue, and are said to resemble the colour of damson cheese; later they change to brownish red. Infarcted areas sink in water. There may be a single large infarct almost occupying one lobe, sometimes only a small one, or several of varying size and age scattered throughout the lungs. In some cases a fortunate section may reveal the embolus with its ensheathing thrombus, but sometimes a thrombus only is found. Microscopically, the alveoli and finer bronchioles are filled with red blood corpuscles, and there is a sharp delimitation from the healthy lung. If the embolus is infective, suppuration occurs, and abscess or empyema ensues.

Symptoms.—If a large embolus blocks one of the main divisions of the pulmonary artery, there is sudden intense dyspnoea, pain in the chest, distress, cyanosis and rapid unconsciousness, death resulting in a few minutes from asphyxia. In other cases the patient gives a short cry, and falls unconscious, death occurring almost immediately from syncope. In some cases unconsciousness develops so rapidly, and the respiratory symptoms are so little apparent, that a cerebral vascular lesion may be suspected. On the other hand, life may be maintained for several minutes or even hours, the patient being unconscious or in acute distress and anxiety with urgent dyspnoea, lividity and cyanosis. Respiration is deep and laboured, but fails to give relief to the sense of suffocation. In such cases also, death may result eventually from asphyxia or syncope, or the patient may slowly recover. In less severe forms, such as occur in cardiac and in some post-operative cases, there is sudden pain with difficulty in breathing, followed in a few hours or in a day or two by cough with hæmoptysis or by the expectoration of deeply blood-stained mucus persisting for some days, and slowly clearing up. If the embolus is infective, fever, often of hectic type, results, sometimes delayed for a day or more.

In the severe cases there is cyanosis, distension of the veins of the neck, acute anxiety with exophthalmos and cold, clammy skin. The only physical signs apparent are the deep, laboured breathing, the harsh breath-sounds, and the evidence of cardiac embarrassment with feeble, failing pulse.

In less severe cases the signs are also not characteristic. There are evidences of cyanosis and distress of less urgent character, possibly some limitation of movement on the affected side, increase of vocal fremitus, localised dullness, with weak or absent breath-sounds and sometimes a pleural rub. In some cases definite bronchial or tubular breath-sounds may be audible. A few fine râles are sometimes present in the adjacent lung areas.

Complications and Sequelæ.—Localised dry pleurisy is almost invariably present. With infective emboli, abscess or gangrene, and later empyema may result. In organisation an infarct leads to a localised area of fibrosis.

Diagnosis.—The dramatic onset, the history and the associated lesions of the veins or heart render diagnosis easy, as a rule; but it may be necessary to eliminate other causes of hæmoptysis, notably pulmonary tuberculosis and chronic venous hyperæmia.

Radiological appearance.—It is possible to have an extensive infarction without any visible radiological change, and in fact it is usually the smaller lesions which can be seen in the form of small peripheral areas of opacity not very clearly defined and occasionally associated with pleural effusion. The diaphragm may be raised.

Course.—As already described, death may occur from asphyxia or syncope in the course of a few minutes or hours, although recovery occurs in some very severe cases. In the less severe forms, after the initial urgent symptoms have passed off, recovery is often rapid and uneventful, save for pain, cough and blood-stained expectoration.

Prognosis.—This depends largely upon the initial shock. The prognosis is very grave when the patient rapidly becomes unconscious. As there is less likelihood of sepsis in cases due to cardiac lesions than in those due to localised venous thrombosis, the prognosis is rather better in the former; but, on the other hand, organisation of a clot in a vein may completely remove the source of the emboli, while the source often persists when they are derived from the heart.

Treatment.—Morphine, pethidine or papaverine should be given to allay the anxiety of the patient. Atropine gr. $\frac{1}{100}$ or $\frac{1}{50}$ is often given but is of doubtful value. Anti-coagulant therapy should be given to prevent further spread and formation of clot. Heparin should be given intravenously in doses of 5000 units 4-hourly for 24 hours. One of the dicoumarol derivatives, such as ethyl-biscoumacetate (Tromexan) or phenylindanedione (Dindevan) should be started at the same time.

Tromexan, 0.3 g., is given three times during the first day and after that three times a day in a dose controlled by prothrombin estimation. Dindevan, 0.1 g., is given morning and evening for the first day and subsequently twice daily in doses controlled by daily prothrombin estimations. After the prothrombin time has been brought to between 20 and 30 per cent of normal, heparin is discontinued and Tromexan or Dindevan is continued in controlled doses. The danger of spontaneous hæmorrhages must be borne in mind. Pulmonary embolectomy has been successfully performed, but unless the services of a surgeon with special knowledge of cardiovascular surgery are available, the patient is more likely to survive if recovery is left to nature.

The danger of too great immobilisation of patients, especially elderly ones, must be borne in mind and whenever possible patients should be allowed to get out of bed for toilet purposes or allowed to sit in a suitable chair at intervals or limb exercises should be regularly performed under supervision.

COLLAPSE OF THE LUNGS

In collapse of the lungs the alveoli are completely or partly devoid of air. The condition may be congenital, and due to non expansion of the lung, when it is referred to as atelectasis. On the other hand, collapse may be the result of removal of the air from lung tissue previously expanded, when it is called apneumatosiis or acquired collapse. The three terms—collapse, atelectasiis and apneumatosiis—are, however, used as synonyms by many writers.

ATELECTASIS OR CONGENITAL COLLAPSE

Ætiology—This condition occurs in still born and in premature infants, and probably persists to some degree for weeks or even months in weakly children. It may result from immaturity or from weakness of the inspiratory muscles, and from obstruction of the air passages by mucus and meconium. It may be a consequence of disease, such as congenital syphilis or lesions and developmental defects of the nervous system.

Pathology—Atelectasiis is due to failure of the respiratory mechanism to draw air into the alveoli and expand them, as occurs normally with the first few inspiratory efforts of the newborn infant.

Atelectatic lungs are solid, airless and small. They are usually described as presenting appearances similar to those of adult liver as regards colour and consistence. In partial atelectasiis the lung appears mottled, and small expanded areas of pinkish colour may project from the surface. The condition is chiefly of medico legal and pathological interest.

APNEUMATOSIS OR ACQUIRED COLLAPSE

There are two types of acquired collapse. That due to obstruction of some part of the bronchial tree and that due to external pressure by fluid, air or diaphragmatic abnormalities. These two conditions have previously been described as active and passive collapse respectively, but Pasteur, who described collapse in a Bradshaw Lecture in 1908, used these terms in quite a different sense since he described as "active", collapse which he thought was due to diaphragmatic paralysis and he used the term "passive" to describe lobular collapse due to bronchial obstruction. The terms are best avoided. This latter type of collapse is sometimes known as absorption collapse as opposed to relaxation or compressive collapse where the primary cause of the collapse is outside the bronchial tree.

The general consensus of opinion now is that collapse is due to bronchial obstruction produced by plugs of mucus, foreign bodies or by swelling of the mucous membrane, bronchial spasm or external pressure. Paralysis of the diaphragm, to which Pasteur gave the premier role, does not of itself produce massive collapse, although immobility or elevation of the diaphragm favours the formation of obstructive plugs on the one hand, and on the other may be the result of the obstruction and consequent collapse.

Synonyms.—Active Lobar Collapse; Massive Collapse.

Ætiology.—The causes are many and various. Foreign bodies in the bronchial tree, neoplasms of the bronchus, granularata usually tuberculous, stenosis of the bronchus as a result of tuberculosis, syphilis or bronchiectasis form an endobronchial group. Compression of a bronchus by mediastinal tumours, aneurysms or pericardial effusions form another.

Then there is the much larger group of post-operative and post-traumatic cases and those occurring in whooping cough, bronchitis, asthma, pneumonia and bronchiectasis. In all these cases the probable common factor is obstruction by retained secretions.

Barium included in post-operative feeds and lipiodol inserted into the mouth during dental operations has shown that pulmonary aspiration is much commoner after operations than is generally realised.

Collapse due to fluid in the bronchial tubes, blood, lipiodol, liquid paraffin and sea water are specially mentioned because they tend to be forgotten.

Collapse of the lung which frequently follows the division of adhesions in artificial pneumothorax is probably due to the trapping of retained secretion, to bronchial stenosis or ulceration or a combination of these factors.

Pathology.—At post-mortem examination the whole of the lung, or a lobe or portion of a lobe may be deflated and retracted towards the hilum. The collapsed area is bluish red, firm, does not crepitate and sinks in water. There are often pneumonic and pleuritic changes but these may be either primary or secondary.

In massive collapse the heart and mediastinum are displaced towards the affected side and the unaffected lobes are distended with air.

Symptoms.—The abruptness of onset depends on the causation and the extent of collapse. Massive collapse of the whole lung and of a whole lower lobe following operation usually has a sudden onset with pain in the lower part of the thorax and behind the sternum. Severe dyspnoea quickly follows and the patient appears dusky, cyanosed and alarmingly ill. There may be a cough but it is often unproductive. The pulse and respiration rate are rapid and the temperature often rises abruptly. Occasionally, especially in old people, the onset is more surreptitious.

The physical signs of massive collapse are usually dramatic. There is immobility of the affected side, often with sucking-in of the ribs. The apex beat is displaced towards the affected side. There is dullness to percussion on the affected side with hyper-resonance on the unaffected. The vocal fremitus is diminished or absent, and the breath-sounds are diminished or absent. Occasionally conduction is increased with bronchial breathing and only the displacement of the apex beat and trachea gives a clue to the true diagnosis, but if the obstruction is in a main bronchus these physical signs are unlikely. Hilar or lobular collapse will give proportionately less physical indications.

Radiological appearances.—The radiological appearances are characteristic, but vary with the extent and duration of the collapse. There will be a homogeneous opacity varying in shape with the lobes involved, accompanied by local and general compensatory emphysema, deviation of the trachea and heart to the side of the lesion and elevation of the diaphragm. Lateral or oblique views are essential.

Complications and Sequelæ.—These depend on the cause of the obstruction and vary from broncho-pneumonia and pulmonary abscess to pleurisy and empyema.

Post-operative cases which survive the abrupt onset usually make a complete recovery when the obstructing mucus is coughed up.

Diagnosis.—The most important conditions from which this malady has to be distinguished are lobar pneumonia, pulmonary embolism, pneumothorax and pleural effusion. The position of the cardiac impulse is often the deciding factor; in collapse it is displaced towards the lung involved, in pleural effusion and pneumothorax it moves away from the affected side, whereas in lobar pneumonia there is usually no cardiac displacement, although there may be dilatation. Labial herpes and blood-stained expectoration are more frequently seen in pneumonia than in collapse. When in right-sided collapse there is marked distension of the left lung with obliteration of the normal cardiac dullness, the signs superficially resemble those of a left-sided pneumothorax; but with careful examination no such error should be made. The distinction from pulmonary embolism may be difficult at first, but the localisation of the signs, and the blood-stained expectoration, may give useful indications.

Course.—The course of the affection in post-operative cases or cases associated with bronchitis, asthma or lobar pneumonia is rapid. After periods extending from 2 to 5 days the temperature falls to normal, the symptoms disappear, the lung quickly re-expands, the heart returns to its normal position and there is complete recovery.

Treatment.—Prophylactic treatment prevents the onset of post-operative collapse. Planned operations should not be carried out on patients with acute respiratory infections or with untreated suppurative conditions of the naso-pharynx. Patients should be encouraged to sit up and move as soon as possible after operation. Those found to have poor pulmonary ventilation before operation should be taught breathing exercises which will be of service both before and after operation. Once the collapse has occurred the object of treatment is to produce cough and expectoration and restore ventilation to the collapsed lung. Tight abdominal binders or strapping should be loosened, the patient laid flat on his back and gently rolled from side to side twelve times. This often results in cough, with expectoration of the obstructing mucus, and the lung rapidly re-expands. This treatment (*Sante manœuvre*) should be repeated every 4 hours if it is not successful at the first attempt. It is surprising how rapidly relief can be obtained by this simple manœuvre even in cases in which the collapse has been present for 2 or 3 days. Stimulant expectorants should be given subsequently for a few days. Postural drainage should be used and tapotage over the affected lung sometimes helps to dislodge the mucus and promote effective coughing. Inhalation of oxygen with 7 per cent. of carbon dioxide promotes deep respiration. Accurate measurements of the daily sputum should be kept. A diminution without clinical improvement is suggestive of recurrence of the obstruction. Bronchoscopic aspiration has been recommended in cases of post-operative massive collapse. Usually no plugs of mucus are seen obstructing the collapsed bronchus.

COLLAPSE DUE TO EXTERNAL PRESSURE.—Pleural effusions, pneumothorax and diaphragmatic displacement also produce collapse of the lung. The latter operates by alveolar compression. The first two operate by separating the two layers of the pleura and allowing the lung to retract. This first stage is known as relaxation collapse. Large effusions or pressure pneumothoraces cause compression collapse which is more complete. High-tension pneumothoraces in patients with a mobile mediastinum sometimes cause collapse of the peripheral portion of the contralateral lung. This form of collapse is described with the conditions which cause it.

COMPLETE CONGENITAL ABSENCE OF A LUNG

Complete congenital absence of a lung is a rare condition, but can be diagnosed by radiographic examination. It is not compatible with a normal expectation of life.

HÆMOPTYSIS

It should be recognised that hæmoptysis is a symptom, not a disease. It is here considered separately because the accurate diagnosis of its origin is essential to its treatment, which differs widely in different conditions

Definition.—The term hæmoptysis is arbitrarily restricted to the expectoration of blood entering the air passages from structural below the larynx or from the larynx itself. When the blood is derived from the naso-pharynx or mouth it is sometimes described as spurious hæmoptysis

Ætiology—1. Pulmonary tuberculosis is the commonest cause, the blood being derived from an aneurysm in a pulmonary cavity, or from ulceration of a small vessel, or congestive processes around the early lesions

2 Chronic venous congestion, particularly in mitral stenosis

3 Bronchiectasis as a result of bleeding from granulation tissue or from ulceration of the bronchiectatic walls. Latent bronchiectasis without sputum may cause recurrent hæmoptysis (*forme hémoptoïque sèche*), this is more common in upper lobe bronchiectasis

4 Inflammatory and destructive diseases of the lungs, air passages or pleura, such as pneumonia, broncho-pneumonia, especially the influenzal variety, abscess and gangrene. Pneumoconiosis, streptotrichosis and ulceration of the larynx, trachea or bronchi from tuberculosis, gumma or new-growth may also be associated with hæmoptysis. Breaking down of a caseous or calcareous bronchial gland is a rare cause, as also is rupture of an empyema through a bronchus

5 Infarction of the lung from embolic or thrombotic obstruction

6 New-growths of the lung, bronchi or mediastinal glands

7 An aortic aneurysm may cause hæmoptysis by "weeping" through an eroded bronchus, or by direct rupture, the latter being, of course, immediately fatal.

8 Traumatic causes.—Injury may cause hæmoptysis, by fractured ribs wounding the lung, by contusion and by breaking down of healed tuberculous lesions. Hæmoptysis occurs frequently in wounds of the chest, both penetrating and non-penetrating. A foreign body, such as a piece of shrapnel, may lie dormant for years, and then cause recurrent hæmoptysis

9 Certain abnormal blood conditions, chiefly leukæmia, purpura, hæmophilia, scurvy, minor degrees of vitamin C deficiency and occasionally pernicious anæmia. Hæmoptysis occasionally occurs in the malignant specific fevers, especially small-pox and measles

10 Parasitic causes, such as pulmonary distomatosis and spirochaetosis, are common in Asia but rare in Europe. Hydatid disease of the lung may cause repeated slight hemorrhages

11 Vicarious menstruation.—Some cases in women have been regarded as vicarious menstruation, and this view dates back to Hippocrates. It is probable, however, that most cases are to be explained as due to leakage from obscure pulmonary lesions

12 Hæmoptysis occasionally occurs in apparently healthy persons. In some, with high systemic arterial tension, it is probable that the pulmonary arterial pressure is also raised, and the condition may be regarded as analogous to the epistaxis which occurs more commonly in such patients. Sometimes the hæmoptysis is due to leaking from an old arrested tuberculous lesion.

13 Rupture of an hepatic abscess or hydatid cyst through the diaphragm into a bronchus is an occasional cause

14 Polyarteritis nodosa is a rare cause of pulmonary hæmorrhage

Spurious hæmoptysis is usually due to staining of the saliva or the pharyngeal secretion with blood, generally derived from the gums, which are spongy and congested, often from early pyorrhæa. The condition is common in anæmic girls, and

is, as a rule, observed in the morning. *Hæmorrhage* from an enlarged pharyngeal vein is often suggested as a cause, but is rarely seen. *Hæmorrhage* after tooth extraction, and staining of the mucus expectorated after epistaxis, are other causes of spurious hæmoptysis.

Pathology.—From the list of causes it might be inferred that the origin of the blood differs in different cases. It may come from the pulmonary or bronchial vessels in pulmonary tuberculosis and other lung or bronchial conditions, and also in chronic venous congestion or infarction. It may come from the thoracic aorta direct, or from some of its branches, in aneurysm and mediastinal new-growth, and from the hepatic vessels in abscess of the liver. In cases due to disease of the trachea and larynx it comes direct from the vessels supplying them.

Post mortem, the larynx, trachea and bronchi may contain clots, or blood-stained froth and mucus, and their walls may be stained in places. Dark-reddish areas of lobular distribution, due to inhaled blood, may be seen in various parts of the lungs, particularly at the bases. Sometimes this may induce bronchitic changes, described as hæmoptoic bronchitis. Careful search in cases of profuse hæmoptysis will usually reveal the source of the hæmorrhage, and in pulmonary tuberculosis this is generally a ruptured aneurysmal dilatation in a cavity or an ulcerated vessel. The aneurysm may be small and escape notice unless many cuts are made into the lung.

Symptoms.—In hæmoptysis, the patient often experiences a tickling in the throat, followed by a gush into the mouth with a salt taste, and on expectoration notices blood. The alarm and anxiety this occasions lead to restlessness and rapid action of the heart. If the bleeding is profuse, cough is frequent, and large clots, together with liquid alkaline blood, may be expectorated to the extent of 20 or 30 oz. in a few hours. The bleeding may cease temporarily, to recur at intervals for several days, until the patient becomes blanched, weak and syncopal, with rapid, weak pulse. In any profuse hæmoptysis, death may occur in a few minutes, either from asphyxia or syncope. In the former case, the blood, at first bright and arterial, is soon dark and frothed, while the patient becomes cyanosed and livid. In slighter degrees of hæmoptysis there may be only streaks, small clots or liquid blood mixed with ordinary sputum. After the actual bleeding has ceased, the sputum may be blood-stained for some days, owing to the expectoration of blood inhaled into other parts of the lungs. This can be recognised by its colour, which varies from dark red to brown, owing to the changes undergone by the blood pigment.

Diagnosis.—This involves two problems—first the differentiation from hæmatemesis and spurious hæmoptysis, and secondly the recognition of the cause of the hæmorrhage. If the patient is seen at the time of the bleeding the first of these is easy. The nature of the blood, and its association with cough and possibly with pulmonary or cardiac signs, are conclusive. When the diagnosis has to be made upon the history given by the patient or by friends it may be difficult, especially in the absence of physical signs.

In hæmatemesis there is frequently gastric pain and faintness before the vomiting, the blood is acid in reaction, dark in colour, even brown from acid hæmatin, and is sometimes mixed with food. The fact that in hæmoptysis blood may be swallowed and subsequently vomited increases the difficulty. Patients often give very dubious answers to questions as to whether the blood was coughed or vomited up. They should then be questioned as to whether sputum was brought up on the following day, and, if so, whether it was blood-stained. In cases of doubt the investigation of the pulmonary and abdominal physical signs, when the patient's condition permits, may decide the diagnosis.

The utmost caution should be exercised to exclude tuberculosis before making a diagnosis of "spurious hæmoptysis". Only when there are no pulmonary symptoms, signs or radiographic indications, and when some obvious cause, such as *anæmia* or *pyorrhæa*, is found, is it safe to do so.

While distinguishing between the various causes of hæmoptysis it is well to regard and to treat it as due to pulmonary tuberculosis until some other cause is conclusively established. The sputum should be examined for tubercle bacilli on several occasions, the temperature recorded and the physical signs including radiographic appearances most carefully watched.

The presence of a valvular lesion, especially mitral stenosis with signs of pulmonary engorgement, may render the cause of hæmoptysis clear. When tuberculosis and cardiac disease can be excluded, a careful study of the history, the symptoms and signs, may throw light on the diagnosis or suggest some investigation which will serve to establish it, e.g. examination of the sputum for parasites and hydatid hooklets, the cytological examination of the blood and radiographic examination.

In other cases, as in bronchiectasis, abscess or gangrene, the history, the physical signs and the nature of the sputum are often characteristic.

In the latent or silent form of bronchiectasis (*forme sèche*), the condition may be revealed only by lipiodol injection.

Bronchoscopy may be of great value in revealing the presence of adenoma or carcinoma. Patients who have had a hæmoptysis which has eluded diagnosis must be kept under observation with radiographic control.

Prognosis—Apart from hæmoptysis due to aneurysm, which is rapidly fatal, or pulmonary tuberculosis, the immediate prognosis in cases of pulmonary hæmorrhage is not unfavourable, even when it continues for days. The ultimate prognosis depends upon the cause.

Treatment—This is so entirely dependent upon the cause and origin of the bleeding that reference should be made to the corresponding diseases.

EMPHYSEMA OF THE LUNGS

Emphysema of the lungs, or alveolar-ectasis, is a condition of distension of the alveoli, it is usually progressive and is associated with definite changes in the inter-alveolar walls. The following varieties are generally recognised—(1) large lunged or hypertrophic, (2) small-lunged or atrophic, (3) compensatory, (4) acute vesicular, and (5) acute interstitial emphysema. The last named condition has no relation to true emphysema except in name, but will be described in this group for convenience.

1 LARGE-LUNGED OR HYPERTROPHIC EMPHYSEMA (SUBSTANTIVE OR IDIOPATHIC EMPHYSEMA)

This is a chronic affection and is usually bilateral.

Ætiology—*Predisposing causes*—It may occur at any age, even in childhood, but is most frequently seen in middle and late adult life. It is commoner in men than in women, probably because they are more exposed to the conditions inducing it. Although not strictly hereditary, it often shows a familial incidence. Certain occupations are credited with being concerned in its production, notably those involving violent or prolonged muscular effort with closed or partially closed glottis, such as blowing wind instruments and lifting heavy weights. Dusty occupations also favour its onset by leading to bronchitis and cough.

The common *exciting cause* seems to be the strain of prolonged and repeated cough, induced by chronic bronchitis, bronchiectasis, asthma, whooping cough, cigarette smoke inhaling and other causes of irritation of the upper air passages.

Pathology.—The pathogenesis of emphysema has been much debated and various explanations have been offered. (1) Primary degeneration theory. Villemin suggested that the essential lesion was a fatty degeneration of the alveolar walls, while Cohnheim believed that there was a congenital defect of the elastic tissue of the lung.

(2) The inspiratory theory, first suggested by Laennec and developed by Gairdner postulates the force of inspiration as the distending agent. (3) The expiratory theory, first enunciated by Mendelssohn, was independently brought forward and established by Jenner. The distension of the alveoli is regarded as due to the effect of forced expiration and cough. Jenner pointed out the special and early involvement of the apices, the anterior and lower margins of the lungs; in other words, the parts least supported by the thoracic cage. (4) Freund regarded the changes in the lungs as secondary to calcification of the costal cartilages, the chest becoming fixed in the inspiratory position and the lung permanently expanded in consequence. Christie in an analysis of these and other theories concludes that there are probably three factors of importance: inflation of the lungs caused by obstruction to expiration; loss of elasticity due to the stress and strain of coughing in asthma; lowered resistance of the lung to wear-and-tear varying from person to person and becoming progressively lower with advancing age.

The characteristic conformation of the chest is usually apparent (see Symptoms), the costal cartilages are often calcified, and on opening the thorax post mortem, the lungs bulge instead of retracting, so that the pericardium may be almost completely obscured. They are pale in colour, even in town-dwellers, a condition called albinism of the lung by Virchow. They are soft and pit on pressure, and, as described by Laennec, give the sensation of a down pillow. The surface of the lung under the pleura shows a finely vesicular appearance, due to the distension of the alveoli, the vesicles often being nearly as large as pins' heads. Not infrequently large bullæ or blister-like protuberances, varying in size from a pea to a Spanish olive, occasionally much larger, may be seen projecting from the surface, particularly at the apices and margins. These bullæ when incised show fine fibrous bands crossing them, the remains of inter-alveolar walls and of atrophied blood vessels. It was formerly customary to refer to such cases as bullous or marginal emphysema and to describe those in which the dilatation is less obvious but more widely diffused as general emphysema; but the conditions are so commonly associated together in varying degrees that little is gained by so doing. On section the lungs are pale and dry, except at the bases, where there is frequently some œdema in advanced cases. The bronchi may show some general dilatation. When bronchitis coexists, mucopus can be squeezed from the cross-sections of these tubes. As pointed out by Fowler, pleural adhesion is relatively uncommon. The infundibula and alveoli are dilated, and the inter-alveolar walls are thin and atrophic, even disappearing wholly or in part. The distension and coalescence of adjacent alveoli result in the formation of bullæ. The calibre of the pulmonary capillaries is diminished by stretching of the alveolar walls, and where atrophy of the inter-alveolar septa occurs the capillaries are destroyed. These two processes result in a considerable diminution in the total aerating surface, and cause the dyspnoea and cyanosis characteristic of the disease. Moreover, the normal anastomoses between the terminal bronchial and pulmonary capillaries increase considerably, and some of the blood in the latter may therefore fail to reach the alveoli and so escape aeration. Atrophic changes in the elastic tissue have been described. In order to maintain the circulation through the diminished capillary area, the right ventricle hypertrophies and the resultant raised blood pressure sometimes induces atheroma of the pulmonary artery. Emphysema being a progressive lesion, and the defective aeration of the blood perhaps interfering with the nutrition of the heart muscle, cardiac failure eventually ensues, causing tricuspid regurgitation, engorgement of the right auricle, and the visceral effects of venous engorgement, such as "nutmeg" liver.

Symptoms.—Dyspnoea of varying degree is the most characteristic symptom. In uncomplicated cases of moderate extent it is only present on exertion, unless bronchitis coexists. In advanced emphysema, dyspnoea is marked and becomes extreme in the bronchiac or "asthmatic" attacks and in foggy weather. Cyanosis

is common, and is to some extent a measure of the degree of emphysema. Varying degrees of polycythemia may be observed. The patient may walk about with a more extreme degree of cyanosis than in any other condition except congenital heart disease. Clubbing of the fingers of moderate degree is common. Cough is usually due to the associated bronchitis, and is worse in the winter and in foggy weather. It is frequent, noisy and often hacking and paroxysmal. Expectoration is also the result of the bronchial catarrh, and varies from a few grey mucoid pellets to copious mucopus.

The chest is enlarged, particularly in the antero-posterior diameter, the upper thoracic spine is rounded and kyphotic, the sternum protrudes forward, and the angle of Louis is prominent, the general effect being the so-called barrel-shaped chest. The ribs run forward more horizontally and the intercostal spaces are wider than normal, the chest being as a whole in the inspiratory position. The respiratory movements are much restricted, the patient elevating the rigid thorax with little expansion on taking a deep breath, so that the inspiratory increase at the level of the nipples may be only $\frac{1}{2}$ to 1 inch instead of the normal $2\frac{1}{2}$ to 3 for an adult. There is often filling and even bulging of the supra-clavicular hollow, while the neck appears short, the sternomastoids stand out, and the jugular veins are full. A zone of dilated venules, the "emphysematous girdle", is often present along the line of the costal attachment of the diaphragm, but is not pathognomonic. The cardiac impulse is not visible, as a rule, and may only be felt with difficulty, but epigastric pulsation is usually apparent. Vocal fremitus is diminished, and the percussion note is hyper-resonant. The superficial cardiac dullness is greatly diminished or even absent, and the lower limit of pulmonary resonance may extend to the costal margin, back and front, the hepatic dullness being encroached on or obliterated.

It is said that in bullous emphysema the breath-sounds are harsh over the outer part of the upper lobes in front, and weak at the bases. In general emphysema the breath-sounds are weak everywhere, inspiration is short and expiration is greatly prolonged. A loud rumbling, from contraction of the thoracic muscles, may entirely obscure the breath-sounds. A few fine bubbling râles may be heard at the bases or at the sternal margins. If bronchitis is present, scattered rhonchi may be audible. Vocal resonance is generally slightly diminished. The heart sounds are weak and distant, and in late stages a tricuspid systolic murmur may develop. The "vital capacity" of the lungs, measured by a spirometer, is often reduced to one-half or less. Radiographic examination shows increased extent, and undue translucency of the lung tissue. It shows the diaphragm lower in position and flattened, and the costophrenic angle widened. The liver is sometimes palpable, possibly from downward displacement by the bulky lung. The spleen may also be depressed and palpable.

Complications.—Bronchitis is the commonest, and often causes a vicious circle. Asthmatic attacks, so called "bronchial asthma", are common in later stages, on the other hand, spasmodic asthma may be the cause of the emphysema. Pneumothorax and interstitial emphysema may occur from rupture of the bullæ, although these accidents are relatively rare or perhaps relatively rarely diagnosed since the difficulties of diagnosis in these cases are obvious. Pneumothorax is a common complication of the severe emphysema of advanced pneumoconiosis. Pulmonary tuberculosis is an occasional complication of emphysema, which, contrary to popular opinion, is not antagonistic to it, although it may mask and obscure the early stages. Right-sided cardiac failure, with its train of consecutive changes, is a late and often terminal complication.

Diagnosis.—This is never difficult in advanced cases. The slighter degrees may be more difficult, and the diagnosis is then largely a matter of inference from the association of chronic cough and dyspnoea, with physical signs of hyper-resonance and prolonged expiration.

Confusion may occasionally arise with pneumothorax and pulmonary tuberculosis.

Careful record of the symptoms and signs and the investigation of the sputum generally suffice to distinguish these conditions. In doubtful cases radiography will assist.

Course—Emphysema is progressive, unless the cause is removed or the effects of the disease are mitigated by residence in a warm, dry climate, especially in the winter. Conversely, residence in unsuitable districts, persistence in detrimental employment, and repeated attacks of bronchitis accelerate its course.

Prognosis—This depends upon the degree of emphysema and the circumstances of the patient. If progressive, it exerts an increasingly crippling effect, and it certainly shortens life under urban conditions. A "vital capacity" of less than 50 per cent. of the normal is of serious import. The advent of severe bronchitis or of cardiac complications may affect the prognosis gravely.

Treatment—Emphysema may be arrested but cannot be cured. Attention must be directed to prevention of the causes of chronic cough and increased intra alveolar tension. In any person with hereditary tendency to emphysema or to winter cough, the questions of occupation and place of residence should be carefully considered. When the disease is established, the patient, if in a position to afford it, should spend the winter in a warm, more equable climate, either abroad or at the south-west coast of England.

Various attempts have been made to increase the respiratory ventilation of the lungs by deflation. The most generally used method is by the use of a well-fitting abdominal belt to raise the diaphragm. Efforts in the same direction have been made by pneumoperitoneum and even pneumothorax. Their justification is doubtful.

Expiration breathing exercises are of general application and quite impressive results can be obtained by their use provided the chest wall is not completely rigid. Even in these cases diaphragmatic movement can be increased.

The diet should be simple and easily digestible, especially in the later stages. If there is spasmodic dyspnoea or asthma, no late meal should be permitted. Clothing should be warm, but the excess of under-garments, often worn in fear of chill, is harmful. Patients should avoid those who have colds and should themselves stay in bed at the first sign of such an infection in themselves.

In other respects treatment is largely symptomatic. In acute bronchitic attacks the measures to be adopted are in no way different from those in bronchitis uncomplicated by emphysema. In the more chronic bronchitis so commonly present in the winter, iodides with alkalis and balsamic expectorants seem beneficial. When asthma or paroxysmal dyspnoea occurs, antispasmodic drugs and measures similar to those used in spasmodic asthma may be employed. When cardiac failure supervenes, the appropriate treatment must be vigorously applied. If there is marked cyanosis and venous engorgement, oxygen administration and diuretic drugs may be employed, and digitalis administered, any associated pulmonary infection, even bronchitis, requires energetic treatment with the appropriate antibiotic, bronchospasm should be treated with antispasmodics.

2. SMALL-LUNGEN EMPHYSEMA (ATROPHIC OR SENILE EMPHYSEMA)

Ætiology—This condition occurs in old age and forms part of the general atrophy of the tissues.

Pathology—The alveolar walls become thinned and disappear, so that adjacent alveoli coalesce. The condition is primarily atrophic, and therefore differs from true emphysema, although the result is to produce a diminished area for aeration. Post mortem the lungs are small and do not bulge or obscure the pericardium. They are often deeply pigmented, and are more spongy than normal, but although bulk occur they are small. On section the lung tissue is bloodless and friable. The bronchi may be slightly dilated and show catarrhal changes.

Symptoms—These are slight and are masked by the enfeeblement due to the

general atrophy and debility. There is shortness of breath only on exertion, or on exacerbation of the chronic bronchitis which is frequently present. The chest is small, flat and thinly covered, the movements are poor and there is elevation of the chest as a whole, with poor expansion. Kountz and Alexander maintain that there is very little diminution in vital capacity, that the movements of the diaphragm are increased and that the intervertebral disks are abnormal. There is little cyanosis, and no clubbing. The vocal fremitus is unaltered or slightly diminished. The percussion note is hyper-resonant, but there is no encroachment on the cardiac and hepatic areas of dullness. Breath-sounds are weak, and there is but little prolongation of expiration. Rhonchi and râles may be heard, especially if bronchitis is present, or if the heart is failing.

Diagnosis.—The condition is generally so obvious that no difficulty arises.

Treatment.—This is chiefly a matter of careful regimen and diet, with treatment of co-existing bronchitis or cardiac failure.

3. COMPENSATORY EMPHYSEMA (LOCALISED OR SECONDARY EMPHYSEMA)

Ætiology.—Localised emphysema is a sequel to some process inducing collapse, contraction or destruction of areas of lung tissue. It may be lobular in distribution in bronchitis, broncho-pneumonia, tuberculosis and diphtheria. It may affect one or more lobes, or the whole of one lung, especially in cases of fibrosis following tuberculosis, pneumonia, chronic pleural effusion and empyema.

Pathology.—It is generally conceded that the inspiratory theory of Laennec and Gairdner satisfactorily explains the genesis of this condition. When shrinkage of an area of lung occurs, the chest wall may fall in if there is pleural adhesion, but otherwise inspiration tends to expand the normal parts of the lungs. None the less, it must be admitted that the expiratory strain of cough may assist in its production.

Although it may be compensatory and physiological at its inception, it is doubtful whether a true hypertrophy takes place after adolescence. In any case it soon leads to atrophy of the alveolar walls, as in true emphysema, and thus becomes pathological and harmful. Post mortem the condition may be found in an upper lobe around contracted scarred lung tissue, or in a lower lobe when the upper lobe is contracted or disorganised. In cases where one lung is fibroid and contracted, compensatory emphysema may be found throughout the sound lung. The resulting adaptations caused by enlargement of one part and shrinking of another may produce some striking displacements, the lower lobe extending upwards nearly to the clavicle, or the anterior margin of the sound lung crossing the mid-line. The general appearances are closely similar to those of ordinary emphysema, except that bullæ do not occur, at any rate until the process is advanced and definitely pathological.

Symptoms.—This condition does not produce symptoms that can be differentiated from those of the primary disease. When it affects a lobe or the whole of one lung, there is hyper-resonance over the area involved, which often contrasts strikingly with the dullness due to the primary lesion. The hyper-resonance may extend across the sternum and even for an inch or more beyond it. The heart is displaced towards the side where fibrosis is in progress. Vocal fremitus and vocal resonance are little altered, but may be increased at first and subsequently diminished. In the early stages, when there is alveolar dilatation without degenerative mural changes, the breath-sounds are exaggerated, harsh or puerile, but when such processes develop, they become weak and there are indications of dyspnoea and cyanosis on exertion.

Diagnosis.—This is easy, owing to the difference between the diseased and "compensatory" areas, and to the indications of contraction and displacement.

Treatment.—No special treatment apart from that of the primary condition is required.

4. ACUTE VESICULAR EMPHYSEMA

Although custom has included this condition with emphysema, it is in reality only a temporary acute distension of the alveoli resulting from any condition causing widespread obstruction of the smaller bronchi. It is sometimes observed after death in cases of acute bronchitis, whooping-cough or asphyxia and in anaphylactic shock, and its existence may be inferred in severe asthma. Post mortem the lungs are bulky and the alveoli distended.

The symptoms are dependent upon the primary condition, although dyspnoea is invariably present. The chest is found to be fully expanded, the vocal fremitus is diminished, the percussion note is hyper-resonant, and the breath-sounds vary with the condition inducing it. In cases due to asthma, the injection of a few minims of 1:1000 adrenaline often produces visible deflation and helps to differentiate it from hypertrophic emphysema.

5. ACUTE INTERSTITIAL EMPHYSEMA

In acute interstitial emphysema air is present in the stroma of the lungs, and in the subpleural connective tissues. It may follow external trauma, such as fractured ribs, or wounds penetrating the lungs. The alveoli may rupture with violent expiratory efforts, as occur in whooping-cough or influenzal broncho-pneumonia. It may occur in diphtheria. The air sometimes tracks along the pulmonary roots to the mediastinum, and appearing in the neck or on the chest-wall gives rise to surgical emphysema.

Post mortem, subpleural bullæ may be seen containing air, and on section of the lung minute air bubbles may be found in the inter-alveolar connective tissue. A diagnosis cannot be made unless the physical signs of surgical emphysema are present. The air is usually completely absorbed, and a perfect recovery takes place. No special treatment is required beyond keeping the patient at rest, and giving sedative drugs to allay cough.

ABSCESS OF THE LUNG

Definition.—Abscess of the lung includes any circumscribed collection of pus formed in the lung tissue, but softened tuberculous areas and bronchiectatic accumulations are usually excluded.

Ætiology.—*Predisposing causes.*—These include any diseases producing general cachexia or malnutrition, notably diabetes and chronic alcoholism, also any conditions leading to diminished resistance locally in the lung, such as injury, disease or exposure.

Exciting causes.—These are pyogenic organisms, which reach the lung by inhalation, by extension from adjacent suppurative processes, or by the blood-stream, either directly or in septic emboli. The common organisms found are streptococci, staphylococci, the pneumococcus, Friedländer's pneumo-bacillus, *Cl. welchii* and *Bact. coli*—sometimes acting in conjunction with putrefactive bacteria. Spirochaetes, *F. fusiformis* and other anaerobic organisms are often present, especially after rupture has occurred. Pulmonary abscess may form under the following conditions:

(1) After inhalation of foreign material into a bronchus. This may be a foreign body, or may occur in association with septic conditions in the nose, naso-pharynx and larynx, or during and after operations in these regions. These are referred to as inhalation abscesses, though some post-operative cases are regarded as due to embolism and not to inhalation. (2) As a result of lobar or lobular pneumonia, especially after the deglutition and aspiration varieties of the latter. Such abscesses are sometimes called meta-pneumonic. (3) Embolic causes—in pyæmia, or following on septic pulmonary emboli due to right-sided septic endocarditis, or derived from distant

septic processes, such as otitis media, and infective thrombo-phlebitis. Amœbic abscess occurs occasionally after dysentery, and pulmonary abscess may be found as a rare complication of enteric fever. (4) From infection of the lung tissue due to spread from adjacent disease. This may occur in bronchiectasis, in ulcerating new growths of the lung, bronchi, œsophagus or mediastinal glands, in caries of the vertebræ or ribs, and in suppurating mediastinal glands. Rupture of an empyema, of a subphreic abscess, of a liver abscess, or of infected hydatid cysts of the lung or liver may also lead to pulmonary suppuration. Ten per cent. of cases of abscess are due to new growths. (5) As a sequel of perforating chest wounds, or of fractured ribs piercing the lung.

Pathology.—Abscess of the lung is generally single and basic when consequent on pneumonia, whereas embolic abscesses are often small and multiple and may be found in any part of the lung. Abscesses due to extension from adjacent disease are generally solitary, and are often large and irregular. The walls of acute abscesses are generally formed of congested and œdematous lung tissue, or of a zone of unresolved pneumonia. Since acute abscesses commonly rupture quickly into a bronchus, a fibrous capsule is unusual, but in chronic abscess there is often considerable fibroid change in the neighbouring lung tissue. The pleura may become involved over superficial abscesses, leading to empyema, or to pyo-pneumothorax if rupture follows.

Symptoms.—Abscess may develop insidiously, with comparatively slight symptoms. More commonly they are an intensification of those due to the primary or antecedent condition. The patient often appears seriously ill, the fever becomes of septic type, remittent or intermittent in character, and of a high range. Rigors and sweating are common. Clubbed fingers are a characteristic and early sign. The pulmonary symptoms at first may be only slight cough with scanty muco-purulent expectoration. Dyspnoea may be present and pain of acute character develops if the pleura is involved. Hæmoptysis occurs in 70 per cent. of cases of abscess. A considerable leucocytosis, up to 20,000 or 30,000 may be found, and occasionally the breath may be offensive, even before rupture into a bronchus occurs, followed by the sudden expectoration of a large quantity of pus. The pus is sometimes unpleasant or offensive-smelling, but has not the extreme fetor of gangrene. Microscopical investigation will demonstrate the presence of pulmonary debris, especially elastic tissue, together with pus cells and micro-organisms. After the expectoration of the pus, the temperature usually falls and the general condition of the patient is much improved, though cough and expectoration persist. In chronic cases after rupture the temperature may become irregular and periodic, a few days of normal temperature being followed by a period of fever and later by increased expectoration. The physical signs in a deep-seated or small abscess are often inconspicuous, and comprise slight dullness over a small area, weak breath-sounds and possibly a few râles in the surrounding infiltrated or œdematous lung tissue. With a large or a superficial abscess, the signs before rupture may be those of consolidated or collapsed lung. After evacuation occurs, the characteristic signs of excavation usually develop at once. In multiple embolic abscesses the signs are usually those of disseminated broncho-pneumonia, and in multiple abscesses due to staphylococcal infection widespread diffuse opacities may be apparent on radiographic examination. These rapidly develop into cavities either empty or with a fluid level. They may be mistaken for lung cysts owing to their thin walls.

Complications and Sequelæ.—The commonest complication is dry pleurisy. This may progress to empyema, or to pyo-pneumothorax, if rupture into the pleura occurs. In some cases mediastinitis or pericarditis may develop. Gangrene is described, but is a rare sequel. Metastatic abscesses may be produced in other parts of the body, especially in the brain, and meningitis is a rare and serious complication. The most important sequelæ are fibrosis of the lung, with bronchiectasis, pleural adhesion and rarely indurative mediastinitis.

Diagnosis.—This is difficult before rupture into a bronchus, but abscess may be suspected from the gravity of the symptoms in relation to the history and signs, especially if leucocytosis and fetor of the breath are present. Radiographic examination may be helpful, by demonstrating a localised shadow before rupture, and excavation afterwards, and also by establishing the situation of the abscess. A fluid level can often be seen in films taken in the erect position, although a fluid level may sometimes be more obvious if the patient is radiographed lying on one or other side or tilted to one side. The sudden expectoration of pus, followed by retrogression of symptoms and signs of excavation is very suggestive of abscess. After rupture has occurred the differential diagnosis has to be considered from :

1. *Interlobar empyema.*—This may be very difficult or even impossible. In this condition the signs are generally most marked in the region of an interlobar septum, there may be some cardiac displacement, and the sputum, though purulent, does not contain elastic tissue.

2. *Bronchiectasis.*—The history, the characteristic cough and sputum, and the variation of the physical signs with the state of the cavity usually suffice to distinguish this condition. A lipiodol or Neo-Hydriol bronchogram will distinguish in doubtful cases, since the oil does not, as a rule, enter abscess cavities and the appearances in bronchiectasis are characteristic.

3. *Gangrene of the lung.*—This is a distinction with little difference except that gangrene is a suppurative condition of the lung that has not localised. The extreme gravity of the patient's general condition and the horrible fetor of the breath and sputum are the most characteristic features of gangrene.

4. *Tuberculous excavation.*—The history, the distribution of the signs and the characters of the sputum, including the presence of tubercle bacilli, are the distinguishing indications.

5. *Purulent bronchitis.*—The history, the widespread physical signs and the absence of elastic tissue from the sputum usually serve to establish the diagnosis, and lipiodol or Neo-Hydriol investigations may be helpful.

In multiple or pyæmic abscesses, it is often impossible to recognise the condition, though it may be suspected from the severity of the symptoms and signs. In any doubtful case radiographic examination or tomography should be carried out, if the condition of the patient permits. The possibility of malignant growth as a cause of abscess should be borne in mind and, when necessary, bronchoscopy as well as lipiodol investigation carried out. Exploratory puncture as a means of diagnosis is dangerous and should be avoided.

Prognosis.—The prognosis though grave in many cases is better than might be anticipated and has been much improved by modern treatment. Pyæmic abscesses have a more serious prognosis except when staphylococcal, which sometimes improved spontaneously even before the days of antibiotics.

Treatment.—Penicillin should be given in doses of 1 to 2 million units daily as soon as the diagnosis is made. When sputum from the abscess is available the sensitivity of the various organisms should be tested in case any of them are penicillin resistant but are sensitive to streptomycin, chloramphenicol, chlortetracycline or other antibiotics. A careful record of the daily amount of sputum must be started and the patient given postural drainage in the position appropriate to the site of the abscess.

The posturing must be kept up for as prolonged periods as possible. Special beds on frames make prolonged postural drainage more effective and more comfortable. Tapotage over the abscess in the correct postural position helps drainage of the abscess and breathing exercises should be combined with the postural drainage. Once the abscess has started to discharge, diminution in the measured amount of sputum should be accompanied by improvement in the clinical condition. If it is not, the drainage is imperfect. Improvement must be correlated with radiological changes.

In a considerable number of cases recovery takes place with penicillin and postural drainage alone.

If in spite of postural drainage and the use of suitable antibiotics, there is no steady progress of improvement from week to week, surgical intervention is called for. The operation of choice in these cases used to be external drainage after the sealing off of the pleura. Resection, however, is more effective when the localisation of the abscess renders the procedure possible.

Bronchoscopic drainage has its advocates and its successes, but it has little advantage if any over postural drainage, except that it is sometimes successful by making the patient cough. Artificial pneumothorax is never advisable in these cases owing to the imminent danger of pyo-pneumothorax.

GANGRENE OF THE LUNG

In this condition localised or diffuse areas of lung tissue undergo putrefactive necrosis.

Ætiology.—Predisposing causes.—These include old age, over-indulgence in alcohol, general debility, diabetes and insanity. In certain rare cases, especially after broncho-pneumonia complicating measles, gangrene of the lung is met with in children.

Exciting causes and associated conditions.—These are, in the main, identical with those of pulmonary abscess (see p. 1002). In addition, the pressure of aneurysm or of new-growth on branches of the pulmonary artery may lead to gangrene. The causal organisms are also very similar to those found in abscess of the lung, and include staphylococci, streptococci, sarcinæ, the *Micrococcus tetragenus*, *Bact. coli*, *Ps. pyocyanea*, *F. fusiformis* with its associated spirochæte, and various anaerobes. Some of these organisms yield putrefactive products, with the liberation of phenol, indole and skatole compounds.

Pathology.—It is not quite clear what are the factors determining whether abscess or gangrene occurs in an infected area of lung. Doubtless the general resistance of the body, the degree of local vascular disturbance and the virulence of the infecting organisms all play their part. Lacnec first described the two varieties of gangrene, the circumscribed and the spreading or diffuse. Around the former there are indications of a line of demarcation, formed by congested lung tissue, which may present the appearance of red hepatisation. The surrounding lung tissue is invariably somewhat œdematous. The gangrenous area is soft and pulpy, and its colour varies from reddish brown to greenish black. As the necrosis advances, putrefactive liquefaction occurs, with the formation of a horribly reeking fluid, containing shreds and masses of necrotic lung tissue. When this is discharged, excavation results, and isolated vessels may be seen running across the resulting cavity, the walls of which are rough and covered with fetid pus. The diffuse variety of gangrene is less common; there is no attempt at a zone of demarcation, and the whole of a lobe or of one lung may be affected. In both forms, the overlying pleura is intensely inflamed, and empyema or pyo-pneumothorax may be produced.

Symptoms.—These are similar to those occurring in abscess of the lung, but are more acute. The patient is desperately ill, rigors are more common and sweating is more profuse. The breath has a peculiar fetor, which, on account of the presence of the skatole group of putrefactive products in the gangrenous lung, has an almost faecal odour. The sputum is intensely offensive, and on standing separates into three layers, similar to those of the expectoration in cases of bronchiectasis. Elastic tissue is usually present. Hæmoptysis is not infrequent and may prove fatal. In rare cases gangrene is not accompanied by fetid expectoration, especially when developing in the insane, in young children, and in diabetics, or after pulmonary embolism.

The physical signs closely resemble those present in cases of pulmonary abscess, and are those of consolidation before liquefaction occurs, and of excavation afterwards. The signs of the antecedent condition such as bronchiectasis, aneurysm or malignant disease may also be present.

Complications and Sequelæ.—These are similar to those met with in pulmonary abscess, but owing to the rapid course and greater fatality of gangrene, they are not so common. Cerebral abscess may occur.

Diagnosis.—The differential diagnosis is as for pulmonary abscess, the distinguishing features being the extremely critical condition of the patient and the revolting fetor of the breath and expectoration. Radiographic examination may give great assistance if the patient's condition permits it to be made.

Course.—The course is usually rapid, unless the diseased area is small and circumscribed. In rare cases of localised gangrene of small extent, resolution and subsequent fibrosis occur.

Prognosis.—This is always extremely grave, though a few cases of localised gangrene recover spontaneously. The prognosis is improved by early operation in suitable cases. The outlook is said to be worse if the condition is apical, and diffuse gangrene is invariably fatal.

Treatment.—Operation is indicated when the general condition of the patient permits, if the gangrenous area can be localised by physical signs or radiographic examination. Exploratory puncture should not be carried out. The other operative procedures are similar to those for abscess of the lung. Operation is contraindicated in cases of diffuse gangrene. The medical treatment is in all respects similar to that for pulmonary abscess. Injections of neo-arsphenamine, in doses of 0.3 g., have given good results, especially in cases due to fuso-spirochaetosis. The sensitivity of the organisms in the sputum to the various antibiotics should be determined, and the appropriate antibiotic given.

PULMONARY FIBROSIS

Synonyms.—Fibroid Disease of the Lung; Chronic Interstitial Pneumonia; Cirrhosis of the Lung.

Definition.—Pulmonary fibrosis is a late sequel of many acute and chronic inflammatory or irritative processes affecting the bronchi, lungs and pleurae. It is therefore rather of pathological than of clinical interest, and in no sense constitutes a separate disease, although the end-results are remarkably similar in different forms. It is described here partly in deference to tradition, and partly to point out the methods of diagnosis between the various causes producing such strikingly similar effects.

Etiology.—(1) The commonest cause is pulmonary tuberculosis, particularly the fibroid and fibro-caseous varieties. (2) The group of pneumoconioses contributes a considerable number of cases, and possibly some varieties of gas poisoning may induce fibroid changes. (3) Broncho-pneumonic processes, particularly the forms associated with measles and whooping-cough, may be followed by widespread fibrosis, especially in children. (4) Although fibroid induration is commonly described as a sequel of lobar pneumonia, this disease is one of the rarer causes. (5) Localised fibrosis may occur around any circumscribed pulmonary or bronchial lesion, such as that produced by syphilis, leprosy, glanders or actinomycosis. Similarly it occurs about infarcts, pulmonary abscesses and parasitic cysts. (6) Chronic venous congestion, if prolonged, leads to fibroid change, which is referred to as "brown induration". This is usually of moderate degree and does not affect the clinical manifestations. (7) Chronic pleural affections, particularly those leading to adhesions or causing pulmonary collapse, may induce fibroid changes within the lung, and these forms are described as "pleurogenous cirrhosis". (8) Any condition causing obstruction

of a bronchus and leading either to collapse or to bronchiectasis may, if long continued, cause fibrosis of the corresponding lung area. Among such may be mentioned inhaled foreign body, new-growth, cicatricial contraction and thoracic aneurysm.

Pathology.—The fibroid overgrowth may be: (1) Massive or lobar; (2) localised or insular; (3) peri-bronchial and (4) reticular.

Any part of the connective tissue framework of the lungs and bronchi may contribute to the fibrosis. In the massive form, which generally affects the whole or the major part of a lobe or even of one lung, the appearances in cases due to tuberculosis differ from those due to other causes. In the tuberculous variety the primary distribution is usually apical, and evidence of other tuberculous processes may be apparent in the form of large or small dried-up cavities, inspissated caseous material or calcareous masses enclosed in fibrous strands. In non-tuberculous processes, the early localisation is commonly basal, and although the primary cause may be obvious in the form of bronchial obstruction or some pleural condition, this is not always the case. On the other hand, non-tuberculous processes may involve the upper lobe primarily and fibroid tuberculosis may fall with special stress upon the lower lobe. In both forms of fibrosis, bronchiectasis may result, although this is more common in the non-tuberculous cases. Apart from the special tuberculous lesions, the end-results are very similar in both forms. The affected area of the lung is shrunken and often devoid of air except for that in the bronchi and in the cavities. It is dark in colour, very firm and hard. On section it presents a mottled appearance owing to the strands of blue-grey fibrous tissue traversing it, contrasting with the pigmented, condensed, airless lung tissue. The fibroid area may be honeycombed by cavities or may present one large excavation, due either to tuberculous cavitation or to bronchiectatic dilatation. There is nearly always thickening and adhesion of the pleura. The contraction of the abnormal fibrous tissue leads to marked displacement of the heart and mediastinum.

The localised form is commonly due to healed tuberculous processes at an apex. There may be simple puckering with or without pleural thickening and adhesion, or a dense mass enclosing dried-up caseous matter or calcareous spicules. In bronchitic or broncho-pneumonic processes a patchy fibrosis may occur, described as insular fibrosis by Fowler.

Reticular fibrosis is a rare condition in which the fibrous tissue in the interlobular septa seems to become increased as well as that around the bronchi. It is at present only of pathological interest.

Symptoms.—The symptoms of pulmonary fibrosis are, in the main, expectoration and dyspnoea together with those of the primary affection. In the non-tuberculous cases, bronchiectasis is so frequently associated that the symptoms and signs found are practically those of this condition. Even in tuberculous cases, some degree of bronchial dilatation is the rule, although the sputum is rarely offensive. The cough is generally periodic and associated with change of posture. The expectoration is abundant, and if bronchiectasis is present, it has the usual characteristic features. The dyspnoea is proportional to the extent of lung involved. It may be extreme in the later stages, when the heart becomes embarrassed and begins to fail. Fever is usually absent, except when complications occur.

The patients are generally spare, although nutrition may sometimes be well maintained until late. They may show signs of deficient aeration in dusky skin, cyanosis and congested cheeks. Polycythæmia sometimes occurs. Clustring of the fingers is almost constant. Evidence of contraction is generally forthcoming in the flattening and retraction of the affected side, with the dropped shoulder and compensatory spinal curvature. Movement is greatly restricted, contrasting with the increased expansion of the other side. The cardiac impulse is sometimes much displaced, especially in left-sided cases, when it may be in the left posterior axillary line or even under the angle of the scapula. In right-sided cases, it is drawn to the right of the

sternum, even sometimes under or outside the right nipple. Vocal fremitus is either increased or diminished, depending on the patency of the bronchus, and percussion gives dullness of varying degree over the fibroid area, while the unaffected parts may be hyper-resonant from "compensatory" emphysema. The diaphragm may be drawn up, and the liver or stomach correspondingly displaced. The breath-sounds may be weak or inaudible but often when a deep breath is taken bronchial breathing can be heard especially if there is underlying bronchiectasis. If there is cavitation the breathing will be cavernous or amphoric. The presence of whispering pectoriloquy is an important indication that bronchial breathing will probably be heard. Vocal resonance will be increased where the breath-sounds are bronchial or diminished if the bronchi are not patent. Adventitious sounds may be entirely absent, and when present vary from rhonchi and bubbling râles to coarse metallic râles, according to the presence or absence of excavation. Radiographic examination gives useful confirmation showing contraction of the rib spaces, scoliosis of the spine to the opposite side, displacement of the trachea and heart to the side of the opacity in which translucent areas of cavitation may be seen occasionally.

Diagnosis.—The diagnosis is usually easy. The evidence of contraction and of mediastinal displacement towards the affected side, especially if signs of cavitation are also present, is highly suggestive. In the absence of the cavitation some difficulty may arise in regard to chronic pleural effusion or empyema. In the earlier stages the contra-lateral displacement of the cardiac impulse should prevent any mistake, but where partial absorption has occurred, this may be very slight or absent. In such cases an exploratory puncture or a radiographic examination may be helpful.

When the diagnosis of pulmonary fibrosis has been made, the differentiation of the cause is an essential to prognosis and treatment. If the condition is apical, there is a presumption in favour of tuberculosis; if basal, some other cause is more probable. Repeated examinations of the sputum should be made for tubercle bacilli, and if these prove negative, radiographic examination may reveal some cause such as new-growth, aneurysm or even foreign body. In some cases a careful consideration of the history may afford a clue to the diagnosis.

Course.—The course is invariably chronic, and may not shorten the natural span of years.

Prognosis and Treatment.—These depend upon the primary condition, but in most cases the latter is mainly symptomatic.

THE PNEUMOCONIOSES

Definition.—A group of lung diseases which result from the inhalation of dust in various trades. Strictly they should be called *Pneumonokonioses*.

Classification.—The pneumoconioses can be considered under headings according to the nature of the dust involved.

1. Silica.
2. Coal.
3. Fibrous silicates.
4. Non-fibrous silicates.
5. Non-pathogenic inorganic dusts.
6. Pathogenic inorganic dusts.
7. Vegetable dusts.
8. Animal dusts.

Nature of dusts.—Dusts consist of particles or aggregates of particles suspended in air and measuring from 150 microns to 0.5 microns in diameter. The sand of deserts, the dust of streets and the pollens of plants are of such large particle size that they become trapped in the nose and upper respiratory passages and never reach the lungs. Industrial dusts result from vigorous mechanical attrition, blasting, grinding, drilling, rubbing, crushing, hammering and sawing. Particles 5 microns or less in diameter can reach the alveoli of the lungs; in the ashed lung specimens of men who have died of silicosis the most representative particle measures 1 micron in diameter.

Reaction of lung tissue to dusts.—Of the dusts which do reach the alveoli silica and fibrous silicates set up different types of fibrous reaction in the lungs and the process is usually progressive. But the dusts of some of the non-fibrous silicates and of the compounds of certain metals, among them calcium, iron, tin and barium seem to be inert when inhaled. They are capable of lying in the lungs for years without inducing any deposition of fibrous tissue or other reaction, but because they are relatively radio-opaque they may produce changes in the X-ray film which must then be distinguished from those of silicosis. The resulting conditions are sometimes referred to as *benign pneumoconioses*. The inhalation of vegetable and animal dusts may cause asthma and bronchitis indistinguishable from these diseases of non-occupational origin.

1. SILICOSIS

Synonyms.—Dust Consumption, Ganister Disease, Grinders' Asthma, Grinders' Consumption, Grinders' Rot, Grit Consumption, Masons' Disease, Miners' Asthma, Miners' Phthisis, Potters' Rot, Rock Tuberculosis, Stone Hewers' Phthisis and Stonemasons' Disease.

Definition.—A disease due to the inhalation of uncombined silica (silicon dioxide). Silicosis and pneumoconiosis must not be used as synonymous terms. Logically, one could classify the pneumoconioses as pneumoconiosis due to silica, pneumoconiosis due to asbestos, pneumoconiosis of coal miners and so on, but such a method would be too cumbersome. Legal considerations make it important that the term silicosis be reserved for that condition caused by the inhalation of uncombined silica, the special characters of which render it capable of being identified when it occurs in typical form. Dusts other than uncombined silica produce pneumoconioses, but these do not present the characters which are possessed by silicosis in its typical form.

Ætiology.—The industries of sandstone quarrying, mining and dressing are the most widespread of all silicosis-producing industries in Great Britain. In various parts of the world the granite industry, the mining of gold, hæmatite iron ore, tin and coal, sandblasting and the manufacture of refractory materials produce cases of silicosis. The severity of the disease depends on such factors as duration and intensity of exposure, dust particle size and, to a large extent, on individual susceptibility. The *solubility theory* of its causation supposes that the fine particles of stone dust which get into the lungs are pathogenic, not because they produce microscopic trauma but because a toxic substance dissolves from their surfaces. This is thought to be silicic acid. It has also been suggested that the rôle of silicic acid in silicotic tissue depends on its degree of polymerisation and that only highly polymerised silicic acids are capable of producing fibrosis.

Pathology.—Round nodules of fibrous tissue, 2 to 5 mm. in diameter, are scattered throughout the lungs. Several may be aggregated together to form large composite nodules or they may be united in a massive fibrosis. Individual nodules may be thrown into sharp relief by emphysema of the surrounding lung, and their centres sometimes undergo calcareous change. Histologically the silicotic nodule is a mass of concentrically laminated dense fibrous tissue, and similar changes are found in

the tracheo bronchial lymph glands Tuberculosis often complicates silicosis and the pathological appearances of the one may obscure those of the other.

Symptoms—There is usually a history of exposure to silica dust of about 30 years' duration, but the latent interval is extremely variable, varying from 6 months to 60 years, and the patient has on occasion left the industry for some years before beginning to complain

Silicosis is generally divided into first, second and third stages, or slight, moderate and severe degrees The first stage, the so called simple silicosis, supervenes in a workman who has been employed in an industrial process involving exposure to siliceous dusts for a period of many years The onset of symptoms is marked by dyspnoea on exertion, slight at first, and later increasing in severity Throughout the illness dyspnoea remains the most important symptom Slight cough may be present from the first. It is usually unproductive or with scanty sputum The general condition of the patient is unimpaired Physical signs in the chest are slight Diminished expansion is scarcely, if at all, present Dullness can rarely be demonstrated, and in older subjects there may be areas of hyperresonance due to emphysema There is no alteration of the breath sounds, and there are no added sounds In this early stage the radiograph shows the presence of discrete nodular shadows, circular and at the most 2 mm. in diameter They may be partially distributed throughout the films, more widespread, or even generalised, but they remain discrete In this stage, impairment of working capacity may be slight or absent

In the second stage dyspnoea and cough become established and further physical signs appear There is diminished expansion of the chest, patchy dullness, sometimes with bronchial breath sounds and scattered rhonchi, especially at the bases The radiograph shows the whole of both lung fields occupied by shadows, indicative of nodulation, and there is some coalescence to form more or less dense opacities There is always some degree of impairment of working capacity In the third stage dyspnoea leads to total incapacity The radiographs indicate areas of massive consolidation Right heart hypertrophy and then failure may supervene Pulmonary tuberculosis may be present in any stage of silicosis It may alter the symptoms, physical signs, radiographic appearances and the whole course of the disease It is the most frequent accompaniment of silicosis Since tuberculosis of the lungs may simulate silicosis in radiographs, no diagnosis should ever be made exclusively on radiographic appearances

Treatment—Silicosis is a man made disease and should be prevented In mining operations ample dilution of the air in the mine with fresh air is the simplest method of reducing the dust concentration Various forms of ventilation are in use Drilling with pneumatic hammer-drills is responsible for much dust, but usually wet drilling can be employed The method used consists of hollow drill steels through which a continuous spray of water passes After shot firing a mist projector is used to allay dust It is really an atomiser using compressed air and spraying a mixture of water containing 0.5 per cent. of castor oil In order to avoid the hazard of dust inhalation no man is allowed to return to the rock face until 8 hours after the blasting charges have been fired

In the grinding trades sandstone wheels should be abolished and replaced by wheels made of harmless synthetic abrasives such as carborundum (silicon carbide) and corundum (aluminium oxide) Where sandstone wheels are still used, the operations of rodding and hacking as well as the actual grinding of metals must be carried out under a continuous stream of water which is drawn away from a trough at the base of the rotating grindstone

In foundries steel and other metals are poured in the molten state into sand moulds, and it follows that the final castings are partly covered with sand and therefore can produce silica dust when treated with particular tools. Fettling (steel dressing) implies the use of a compressed air chisel to clean up a casting Locally applied

exhaust ventilation must be used in such an occupation. Where castings and other metal objects are cleaned by sandblasting, the man wears a special dress, so arranged that he breathes pure air from outside the sandblasting cabinet. It is better to use shot-blasting in which crushed ball-bearings replace sand. The steel powder resulting is harmless. The hydro-blast is the safest apparatus used to clean castings. A high velocity jet of sand and water is projected on to castings, thereby removing moulding material, cores and scale. The velocity of the water as it leaves the hydro-blast gun is in excess of 3 miles per minute. In all these trades where it is found impossible to control the dust completely the worker must wear either a dust mask or an air-line breathing apparatus.

Pre-employment clinical and radiographic examinations of the chest are essential. Periodical radiographic examinations enable silicosis to be detected at an early stage. They therefore help to get men out of a dusty industry before damage to the lungs has gone too far. They are also a means of discovering men with pulmonary tuberculosis who not only expose themselves to additional risk by remaining in the dusty occupation but are possible sources of infection to their fellow-workers.

2. PNEUMOCONIOSIS OF COAL MINERS

Synonyms.—Pneumoconiosis of Coal Workers, Coal Miners' Asthma.

Definition.—A dust disease of coal workers slowly disabling and quite different from classical silicosis. The rise in its incidence, particularly in South Wales since 1925, can be related to the great increase in the amount of dust which has followed the mechanisation of the industry.

Ætiology.—The bulk of cases occurs in colliers working at the coal face, and to a less extent among other underground workers. That the disease is also found in surface workers on the screens and in coal trimmers at the docks strongly suggests that the causative agent is coal dust and not silica. Classical silicosis occurs in only the small percentage of coal miners who are exposed to silica dust in the occupations of ripping, hrushing, driving a hard heading and driving a cross measure drift, but both coal pneumoconiosis and silicosis are often indistinguishably combined. The highest incidence of the disease is found in the mining of high rank coal or anthracite; it is less common in medium rank or steam coal mines, and least common in low rank or bituminous coal mines.

Pathology.—Throughout the lungs coal dust collects in foci around the small bronchioles and their accompanying arteries, and a diffuse network of reticulin fibres is laid down around these foci. In certain cases the air spaces around the coal foci become dilated, an appearance described as *focal emphysema*; these emphysematous spaces may enlarge and become confluent, although bullæ projecting from the surface of the lung do not occur. In other cases a progressive coalescent collagenous fibrosis occurs, leading to the formation of nodules and later to a massive fibrosis. This fibrosis may be due to a sporadic factor such as silica, with possibly a complicating tuberculosis infection. In some cases the changes of tuberculosis predominate.

Symptoms.—The clinical course of the illness may cover many years, and routine radiographic examinations usually show changes in the lungs before the onset of symptoms. Dyspnoea and cough productive of coal black sputum are the most prominent, the chest becomes emphysematous and there may be clubbing of the fingers. The earliest radiographic change is a fine network of pinhead shadows, sometimes sharp and lace-like but much more often blurred. Such shadows are variously known as *reticulation* or *pinhead mottling*. They are followed by the stage of *nodulation* where the nodules are 2 to 5 mm. in diameter. The next stage is one of coalescent nodulation, and in more advanced cases there are multiple less well-defined fluffy shadows. Large well-defined, dense massive shadows are seen in advanced cases of *progressive massive fibrosis*. Focal emphysema cannot be diagnosed in life but its

presence may be suspected when there is intense dyspnoea leading to death from respiratory or right heart failure. Where the changes are those of massive fibrosis, progression is less rapid unless active pulmonary tuberculosis, unresponsive to treatment, supervenes. The course of pulmonary tuberculosis is generally modified by coal pneumoconiosis and often its presence cannot be identified confidently in life. This is in contrast with the severe type of infection which occurs in patients with silicosis. Thus in coal pneumoconiosis the miner is more breathless than ill and dies of *miners' asthma*, whereas in silico-tuberculosis he is ill as well as breathless and dies of *miners' phthisis*.

Treatment.—As in the case of silicosis treatment is entirely symptomatic. Young men with quite advanced simple pneumoconiosis are usually not seriously disabled, whereas men with progressive massive fibrosis are much disabled and their disability increases both with age and with deterioration in radiographic appearances. It has been shown that simple pneumoconiosis does not progress in the absence of further exposure to coal dust, whereas massive fibrosis is nearly always progressive whether or not dust exposure ceases. This is a strong argument in favour of periodic radiographic examinations. Measures directed towards dust suppression are wet cutting, wet drilling, water infusion of the coal face and hand spraying of the coal face before the coal is pulled down. Adequate ventilation is, of course, essential in reducing dust concentration.

3. FIBROUS SILICATES

The fibrous silicates include asbestos, talc, sillimanite and sericite.

(a) ASBESTOSIS

Ætiology.—Asbestos is the name given to a series of minerals composed of the silicates of magnesium and iron crystallised in silky and fibrous form. Canada produces 65 per cent. of the world's asbestos. It is mined both in open pits and by underground methods. In Great Britain the main processes involved in the asbestos industry include the crushing and disintegration of the raw material, carding and card cleaning and finally the spinning of the yarn and weaving of the cloth. Besides being woven, asbestos is ground and mixed with cement and plastics to make insulating slabs and many other articles. Asbestosis can follow employment in any of these processes but the risk is greatest in the crushing, disintegrating, carding and card cleaning processes, where there is most dust. It seems that the fibrosis is caused by mechanical irritation from the asbestos fibres during the movements of respiration, and that this peculiarity is related to the flexibility of the fibres not possessed by other foreign bodies.

Pathology.—Large areas of the lung are tough owing to the presence of fibrous tissue; emphysema, although extensive, is usually localised to the lower and apical parts of the lungs, and there are many pleural adhesions. On histological examination the alveolar walls are diffusely thickened, there is generalised fibrosis and throughout the lung tissue are seen fibres of asbestos and asbestosis bodies.

Symptoms.—The average length of exposure before the onset of symptoms is 7 years. Dyspnoea is the most conspicuous symptom and it may be out of proportion to the signs found in the chest. There is often a non-productive cough with pain between or under the shoulders, and behind the sternum, but hæmoptysis does not occur except in the presence of pulmonary tuberculosis. Clubbing of the fingers is not uncommon; examination of the chest shows limitation of respiratory excursion, sometimes with medium crepitations of a metallic tone in both bases. Asbestos bodies are found in the sputum. These are golden-yellow structures of beadlike form, elongated and often with bulbous ends and varying in length from 20 to over 200 microns. An asbestos fibre forms the central core in the body.

The radiograph shows a diffuse ground-glass or fine cobweb appearance, mainly at the lung bases. It changes later into a fine punctate stippling and extends to involve the middle and upper zones, although the extreme apices usually remain unaffected. The interlobar pleura is thickened and there is a shaggy appearance to the heart outline.

Prognosis.—Fibrosis develops more rapidly than in the case of silicosis and death may occur within 5 years of the onset of symptoms. The incidence of associated pulmonary tuberculosis although not as high as in silicosis, is significant. Bronchial carcinoma supervenes in more than 10 per cent. of cases.

Treatment.—Treatment is symptomatic only. In asbestos mining wet-rock drilling is imperative. In factories and textile mills the principle of locally applied exhaust ventilation must be enforced to prevent the escape of asbestos dust into the air of any room in which work is done. Suppression of dust in the cleaning of carding machines is best ensured by the use of a revolving brush fitted with a cover and connected to a portable vacuum cleaner. By the use of closed-in machines handling should be reduced to a minimum. Dust washes must be used where necessary. In Great Britain legislation has been so effective in controlling the disease that, with few exceptions, cases now diagnosed have industrial histories going back before 1931.

(b) TALCOSIS

Talc is a hydrated magnesium silicate. It is used as a toilet powder, as a dusting agent for rubber tyres and gloves, in ceramics and in the manufacture of paper. Talc pneumoconiosis has occurred mostly in the mining and milling industry. Disability is less than might be suggested by the radiographic appearance of nodular shadows distributed diffusely over both lung fields. There is, however, an increased susceptibility to pulmonary tuberculosis.

(c) SILLIMANITE PNEUMOCONIOSIS

The sillimanite group of minerals are all aluminium silicates and are used in the manufacture of high-grade refractories. Radiographic and histological changes have been found in workers exposed to the dust, although there is no disability.

(d) SERICITE PNEUMOCONIOSIS

Sericite, which is a fibrous variety of muscovite, has, without justification, been suggested as a cause of pulmonary disease. The fibre particles are too small to produce the sort of reaction which is found in asbestosis; they are, however, often present in the lungs of miners with silicosis because of the association of sericite with quartz.

4. NON-FIBROUS SILICATES

The minerals in this group are complex aluminium silicates combined with potassium, magnesium or iron. When inhaled as dusts, they cause no disability but are capable of producing the radiographic changes of pneumoconiosis.

(a) MICA

Mica is transparent and heat resistant, and is therefore used for the chimneys of oil lamps and for peep-holes in furnaces and stoves. Because of its high resistance

to the passage of electricity it is one of the essential minerals in the electrical industry. Radiographs of workers exposed to mica dust have shown diffuse shadows in the middle zones of the lungs, sometimes with fibrosis of the peribronchial type.

(b) FULLER'S EARTH

Fuller's Earth is an absorbent of grease and is used for the filtration of mineral oils, and as an ingredient of soap, wall papers and toilet requisites. Fine punctate mottling with some coalescence has been described in the radiographs of men exposed to the dust. The necropsy appearance is that of a soft, patchy pneumoconiosis unlike the hard nodular appearance of silicosis.

(c) KAOLIN

Kaolin or china clay is used in the manufacture of paper, in ceramics, as a filler in the rubber industry, for paints, for wall plasters and white Portland cement. Extremely fine mottling or reticulation has been described in the radiographs of a number of workers exposed to the dust.

5. NON-PATHOGENIC INORGANIC DUSTS

The dusts of the salts of calcium, iron, tin and barium are inert when inhaled, and give rise to the *benign pneumoconioses* (see p. 1009). Particles small enough to enter the alveoli are engulfed in phagocytes which are either coughed up or deposited in the aggregations of lymphoid tissue at the bifurcations of the bronchioles. Radiographic shadows may be produced, the density of which varies directly with the atomic weight of the element in the compound concerned. Calcium (atomic weight, 40), inhaled as the dust of limestone, marble, lime or cement, may give rise to non-progressive, arborescent shadows. Iron (atomic weight, 56) can cause reticulation or nodulation. The radiographic appearances in the chest of an electric arc welder may be identical with those of silicosis but *welders' siderosis* can be distinguished from silicosis by the complete absence of disability. *Stannosis*, a condition which results from the inhalation of salts of tin (atomic weight, 118) gives rise to scattered dense punctate shadows with no associated symptoms or abnormal physical signs. In *baritosis* or barium pneumoconiosis (atomic weight, 137) there is no disability, but in radiographs there are small sharply circumscribed nodules evenly distributed throughout the lung fields.

6. PATHOGENIC INORGANIC DUSTS

Aluminium is capable of producing fibrotic pulmonary lesions, and manganese, cadmium and vanadium give rise to chemical pneumonitis. Both types of reaction can follow the inhalation of beryllium and its compounds (see p. 385).

(a) ALUMINOSIS

Exposure to the inhalation of aluminium dust in Germany during the War of 1939-1945 gave rise to a condition known as *aluminosis* or *aluminium lung*. The development of the illness was rapid and appeared to bear no relation to the length of exposure to the dust. A dry cough with pain on breathing, shortness of breath, anorexia and gnawing abdominal pain were the main symptoms. Radiographs showed focal shadows in the apices with a reticular appearance in the upper and middle zones, later becoming confluent. Spontaneous pneumothorax occurred in a few of the cases.

(b) PNEUMOCONIOSIS IN BAUXITE SMELTERS (SHAVER'S DISEASE)

Between 1941 and 1943 *aluminosis* occurred at Niagara in men exposed to fume in the manufacture of the abrasive corundum (Al_2O_3), a form of artificial emery. They heated bauxite, an ore containing 80 per cent. Al_2O_3 and up to 7 per cent. SiO_2 , with iron and coke in the electric ore at 2000°C . Some of the bin men, furnace feeders and overhead crane men developed diffuse fibrosis of the lungs with emphysematous bullae but without silicotic nodules. There were 13 deaths from pneumothorax. One man had 8 pneumothoraces and he is the only man seriously affected who still lives. Meanwhile tuberculosis has not developed in the lungs of the survivors.

7. VEGETABLE DUSTS

Chronic lung disease sometimes results from the prolonged inhalation of the dusts of bagasse, cotton, derris, flax, flour, gum arabic, grain, hay, hemp, jute, linseed, malt, nuts, paprika, sisal, straw, tea and wood. It usually takes the form of chronic bronchitis, indistinguishable from non-occupational bronchitis, and it is not accompanied by any characteristic radiographic appearance.

(a) COTTON

Four conditions affecting the respiratory system are described in workers exposed to cotton dust in different parts of the world. These are mill fever, byssinosis, weavers' cough and an acute illness occurring among people who handle low-grade stained cotton.

(1) *Mill Fever*.—Almost all workers suffer from *mill fever* or *cotton cold* when they begin to work in the cotton mills, and a similar illness occurs on first exposure to the dusts of flax, grain and malt. Tolerance is established usually within a few days, though symptoms may reappear following an absence from work for a time as short as 2 to 4 weeks. Mill fever begins within 12 hours of exposure to the dust. The temperature may rise as high as 103°F . but returns to normal over night. Headache, malaise and exhaustion accompany the fever, and occasionally nose-bleeding, nausea and vomiting occur. Symptoms may reappear each night for the first few days, or even weeks of exposure but most workers become acclimatised within the first month.

(2) *Byssinosis*.—

Synonyms.—Strippers' Asthma, Grinders' Asthma, Cotton Card Room Asthma.

Ætiology.—The illness begins suddenly after many years of exposure to dust in the cleaning and carding of cotton, especially in men who strip and grind the carding machines.

Symptoms.—Three stages are recognised in its development. In the first stage, the worker complains of an irritating cough with tightness in the chest and breathlessness usually on Monday, hence the name *Monday fever*, and he remains well for the rest of the week. In the second stage the symptoms extend over more days in the week and finally become permanent. In the third stage the byssinosis is disabling; tightness of the chest and dyspnoea due to chronic bronchitis and emphysema are so distressing that the worker has to leave the cotton industry.

Treatment.—The condition is reversible only in the early stages and for recovery to take place there must be complete withdrawal from exposure to cotton dust. The treatment of chronic bronchitis and emphysema is discussed on p. 1000.

(3) *Weavers' cough*.—This is an acute illness confined to workers employed in cotton weaving sheds. Outbreaks have always been associated with the handling of mildewed yarn, which suggests that the causal agent is a fungus. Tightness of the chest, retrosternal pain, dyspnoea and cough productive of purulent sputum are the

to the passage of electricity it is one of the essential minerals in the electrical industry. Radiographs of workers exposed to mica dust have shown diffuse shadows in the middle zones of the lungs, sometimes with fibrosis of the peribronchial type.

(b) FULLER'S EARTH

Fuller's Earth is an absorbent of grease and is used for the filtration of mineral oils and as an ingredient of soap, wall papers and toilet requisites. Fine punctate mottling with some coalescence has been described in the radiographs of men exposed to the dust. The necropsy appearance is that of a soft, patchy pneumoconiosis unlike the hard nodular appearance of silicosis.

(c) KAOLIN

Kaolin or china clay is used in the manufacture of paper, in ceramics, as a filler in the rubber industry for paints for wall plasters and white Portland cement. Extremely fine mottling or reticulation has been described in the radiographs of a number of workers exposed to the dust.

5 NON-PATHOGENIC INORGANIC DUSTS

The dusts of the salts of calcium, iron, tin and barium are inert when inhaled and give rise to the *benign pneumoconioses* (see p 1009). Particles small enough to enter the alveoli are engulfed in phagocytes which are either coughed up or deposited in the aggregations of lymphoid tissue at the bifurcations of the bronchioles. Radiographic shadows may be produced, the density of which varies directly with the atomic weight of the element in the compound concerned. Calcium (atomic weight, 40) inhaled as the dust of limestone, marble, lime or cement, may give rise to non progressive arborescent shadows. Iron (atomic weight, 56) can cause reticulation or nodulation. The radiographic appearances in the chest of an electric arc welder may be identical with those of silicosis but *welders siderosis* can be distinguished from silicosis by the complete absence of disability. *Stannosis*, a condition which results from the inhalation of salts of tin (atomic weight, 118) gives rise to scattered dense punctate shadows with no associated symptoms or abnormal physical signs. In *baritosis* or barium pneumoconiosis (atomic weight, 137) there is no disability but in radiographs there are small sharply circumscribed nodules evenly distributed throughout the lung fields.

6 PATHOGENIC INORGANIC DUSTS

Aluminium is capable of producing fibrotic pulmonary lesions, and manganese, cadmium and vanadium give rise to chemical pneumonitis. Both types of reaction can follow the inhalation of beryllium and its compounds (see p 385).

(a) ALUMINOSIS

Exposure to the inhalation of aluminium dust in Germany during the War of 1939-1945 gave rise to a condition known as *aluminosis* or *aluminium lung*. The development of the illness was rapid and appeared to bear no relation to the length of exposure to the dust. A dry cough with pain on breathing, shortness of breath, anorexia and gnawing abdominal pain were the main symptoms. Radiographs showed focal shadows in the apices with a reticular appearance in the upper and middle zones later becoming confluent. Spontaneous pneumothorax occurred in a few of the cases.

(b) PNEUMOCONIOSIS IN BAUXITE SMELTERS (SHAVER'S DISEASE)

Between 1941 and 1943 *aluminosis* occurred at Niagara in men exposed to fume in the manufacture of the abrasive corundum (Al_2O_3), a form of artificial emery. They heated bauxite, an ore containing 80 per cent. Al_2O_3 and up to 7 per cent. SiO_2 , with iron and coke in the electric ore at $2000^\circ C$. Some of the bin men, furnace feeders and overhead crane men developed diffuse fibrosis of the lungs with emphysematous bullæ but without silicotic nodules. There were 13 deaths from pneumothorax. One man had 8 pneumothoraces and he is the only man seriously affected who still lives. Meanwhile tuberculosis has not developed in the lungs of the survivors.

7. VEGETABLE DUSTS

Chronic lung disease sometimes results from the prolonged inhalation of the dusts of bagasse, cotton, derris, flax, flour, gum arabic, grain, hay, hemp, jute, linseed, malt, nuts, paprika, sisal, straw, tea and wood. It usually takes the form of chronic bronchitis, indistinguishable from non-occupational bronchitis, and it is not accompanied by any characteristic radiographic appearance.

(a) COTTON

Four conditions affecting the respiratory system are described in workers exposed to cotton dust in different parts of the world. These are mill fever, byssinosis, weavers' cough and an acute illness occurring among people who handle low-grade stained cotton.

(1) *Mill Fever*.—Almost all workers suffer from *mill fever* or *cotton cold* when they begin to work in the cotton mills, and a similar illness occurs on first exposure to the dusts of flax, grain and malt. Tolerance is established usually within a few days, though symptoms may reappear following an absence from work for a time as short as 2 to 4 weeks. Mill fever begins within 12 hours of exposure to the dust. The temperature may rise as high as $103^\circ F$. but returns to normal over night. Headache, malaise and exhaustion accompany the fever, and occasionally nose-bleeding, nausea and vomiting occur. Symptoms may reappear each night for the first few days, or even weeks of exposure but most workers become acclimatised within the first month.

(2) *Byssinosis*.—

Synonyms.—Strippers' Asthma, Grinders' Asthma, Cotton Card Room Asthma.

Ætiology.—The illness begins suddenly after many years of exposure to dust in the cleaning and carding of cotton, especially in men who strip and grind the carding machines.

Symptoms.—Three stages are recognised in its development. In the first stage, the worker complains of an irritating cough with tightness in the chest and breathlessness usually on Monday, hence the name *Monday fever*, and he remains well for the rest of the week. In the second stage the symptoms extend over more days in the week and finally become permanent. In the third stage the byssinosis is disabling; tightness of the chest and dyspnoea due to chronic bronchitis and emphysema are so distressing that the worker has to leave the cotton industry.

Treatment.—The condition is reversible only in the early stages and for recovery to take place there must be complete withdrawal from exposure to cotton dust. The treatment of chronic bronchitis and emphysema is discussed on p. 1000.

(3) *Weavers' cough*.—This is an acute illness confined to workers employed in cotton weaving sheds. Outbreaks have always been associated with the handling of mildewed yarn, which suggests that the causal agent is a fungus. Tightness of the chest, retrosternal pain, dyspnoea and cough productive of purulent sputum are the

main symptoms, malaise, fever, frontal headache and aching pains in the limbs and back may also be present

(4) *Acute respiratory illness from contaminated cotton*—Contamination of cotton with *Aerobacter cloacæ* has been responsible for epidemics of an acute febrile condition in workers exposed to its dust. Symptoms begin within the first 6 hours of exposure and include anorexia, headache, vomiting, cramp like abdominal pain and sometimes rigors. The illness usually persists for 2 to 5 days

(b) FARMERS' LUNG

This condition follows the inhalation of the dust of mouldy hay or grain, and fungus infection is probably a factor in its aetiology, although its exact role has not been determined. Cowmen and members of mobile threshing teams are especially at risk. The clinical picture is that of chronic bronchitis and emphysema, which becomes progressively more severe with continued exposure. Radiographs in the early stages show a fine alveolar mottling with evidence of compensatory emphysema. In the later stages there is an increase in the density of the mottling, and patches of opacity due to coalescent areas of fibrosis appear, with increase in the hilar and peripheral shadows. The patient must be removed from dusty work and treated with potassium iodide. The prognosis is good.

(c) BAGASSOSIS

Bagasse is the cellulose fibre of sugar cane which remains after the sugar has been extracted. It is used for making boarding for the interior decoration of buildings and for thermal insulation. Exposure to the dust occurs when workers use a shredding machine to break up the bales of bagasse. The dust may give rise to a self limited respiratory infection with acute bronchiolitis, severe dyspnoea, cough productive of scanty sputum and sometimes hæmoptysis. Radiographs show hilar shadows throughout the lung fields. There is usually gradual improvement with recovery in 6 weeks. Rarely impaired resolution occurs and may lead to pulmonary fibrosis with the radiographic appearance of thick bands of fibrous tissue traversing the lung fields and simulating cavities.

(d) PAPRIKA

In Hungary and Yugoslavia along the Danube the fruits of the paprika plant when picked late in the season are often infected with the mould *Mucor stolonifer*. The dried fruits are made into red pepper, and inhalation of the spores and mycelia by the paprika splitters may give rise to acute bronchitis and later to fibrosis of the lungs and bronchiectasis. The grinders and packers of the red pepper never suffer in this way.

(e) WOOD

Bronchial asthma can be due to allergy to wood dusts, in particular to those of the South African boxwood (*Gonoloma kamassi*), mansonia wood (*Sterculiaceae altissima*) and Western red cedar (*Thuja plicata*). Gum acacia is the allergen responsible for printers' asthma, which occurs in men exposed to a spray used in colour printing to offset one printed page from the next. It can be eradicated by the substitution of dextrose for gum acacia in the spray fluid.

8. ANIMAL DUSTS

The dusts of leather, silk, wool, fur, hair, bone, horn and ivory are of minor importance in the causation of respiratory disease. On the other hand the danders of cat, dog and horse, and the feathers of birds, may be responsible for asthma. Animal dusts sometimes carry infections, especially anthrax (see p. 79).

DONALD HUNTER.

PULMONARY TUBERCULOSIS

Synonyms.—Phthisis; Consumption.

Pulmonary tuberculosis embraces all the abnormal conditions induced by infection of the lungs, pleuræ and bronchial glands with the tubercle bacillus.

Ætiology.—**Predisposing Causes.**—**Age.**—The maximum age incidence is between the fifteenth and forty-fifth years, although the disease may be encountered at any age. Senile tuberculosis is more common than is generally recognised.

Sex.—The disease is more frequent in males, but between the ages of 5 and 15 the female sex shows a preponderance.

Heredity.—Pulmonary tuberculosis certainly occurs with undue frequency in certain families. Since the direct transmission of the tubercle bacillus to the infant is extremely rare, two explanations seem possible—(1) Children born of tuberculous stock may inherit an increased susceptibility or diminished resistance, the tuberculous diathesis; or (2) they may contract tuberculosis on account of their exposure to massive infection in early life.

Race.—Native races suffer severely when first exposed. In Europe people from isolated rural areas who migrate to cities are particularly susceptible, with a high mortality and a high morbidity; long urbanised races like the Jews are said to be relatively resistant.

Occupation.—The highest mortality from tuberculosis occurs in England amongst the workers in dusty occupations, and conditions leading to overwork or to underfeeding increase the liability to the disease.

Environment.—Overcrowding, defective sanitation, dampness, dirt, lack of sunlight and insufficient ventilation are most potent factors in the spread of the disease, causing both lowering of the resistance and increased facilities for direct infection.

Trauma.—Trauma, involving the chest-wall, may be followed by active pulmonary tuberculosis. This is probably because the injury leads to activity of previously arrested disease, rather than to fresh infection at a spot of lowered resistance.

Psychological.—Psychical factors, such as sudden mental shock, grief or disappointment, may influence the outcome.

The influence of other diseases and conditions.—The following diseases predispose to the development of pulmonary tuberculosis: measles, especially when complicated by broncho-pneumonia, whooping-cough, influenza, pneumoconiosis, alcoholism, diabetes, syphilis, congenital heart disease and insanity. Tuberculosis may manifest itself for the first time during prolonged lactation or after repeated pregnancies; when previously existent it often remains quiescent during pregnancy, but it may spread rapidly after childbirth. Contrary to the usual belief, pulmonary tuberculosis not infrequently coexists with mitral stenosis. Cases apparently following pneumonia, pleurisy or bronchitis are usually tuberculous from the onset.

EXCITING CAUSES.—The causal organism is the *Mycobacterium tuberculosis*, discovered by Koch in 1882. It exists in four main forms, human, bovine, avian and reptilian; only the two former usually occur in man, but avian infection has been recorded. The human type is found in over 97 per cent. of pulmonary tuberculous lesions, though a higher proportion of the bovine type has been found in Scotland. In glandular tuberculosis up to the age of 5 years, over 80 per cent. of the bacilli

isolated conform to the bovine variety. In tuberculosis of bones and joints up to the same age, 29 per cent. of the cases are of bovine origin.

The bacilli may gain access to the body by inhalation, by alimentary ingestion, through the tonsils, through the skin, or possibly, in rare instances, by hereditary transmission. It is probable that in the majority of cases of pulmonary tuberculosis in adults, the organisms are carried direct to the lungs in the inspired air, and Ghon showed that in children, who had died of tuberculosis of the lungs, a primary focus was present in the lungs in 92.4 per cent. Calmette and others have demonstrated that the bacilli may gain access to the bronchial glands from the alimentary tract through the thoracic duct, or from the tonsils through the cervical and mediastinal glands but this is now considered to be an exceptional path of infection. Cases have been recorded in which primary cutaneous infections have been followed later by active pulmonary tuberculosis. Direct intra-uterine transmission of the tubercle bacillus if it occurs at all, must be so rare that it is a factor of negligible importance.

The incubation period of tuberculosis is uncertain owing to the difficulty of determining when infection takes place. It is believed by many authorities that the majority of individuals in a semi-rural or semi-urban country like Great Britain are originally infected in infancy, early childhood or youth by the inhalation of bacilli in infected spray droplets or dried dust, or else by ingestion of bovine or occasionally human bacilli. The inhaled bacilli produce a lesion in the tissue known as a primary lesion which has special characteristics.

The focal lesion is relatively slight but the reaction in the regional glands is much more obvious and characteristic. Three possible things may happen as a result of the tuberculous lesion. The lesion may disappear, leaving little or no trace, the focal lesion and the regional glands may become fibrous and then calcified as described by Ghon; or the focal lesion or the glands may break down and infection may spread locally or generally through the blood-stream.

What happens in an individual infection depends on the dose of infection, the age and general condition of the infected person and possibly the degree of inherited resistance to tuberculous infection. The earlier the age at which infection takes place, the more serious the result.

Following infection, acquired resistance develops to a greater or lesser extent and is probably permanent. The acquired resistance modifies the effect of any subsequent infection so that in post-primary tuberculosis there is a much more severe focal reaction than in the primary infection and little or no regional glandular reaction. It has been held that reinfection does not take place but that all tuberculosis subsequent to the primary infection is a reactivation or a spread from the original focus just as tertiary gummata in syphilis are not evidence of reinfection but of spread from an original primary chancre. This theory would tend to discount the danger of contact infection in later life, but, in fact, there is a great deal of evidence to show that reinfection is the common cause of post-primary tuberculosis.

Pathology.—The earliest lesion in the lung is the formation of tubercles whose structure is described in the general article on tuberculosis. Whereas pulmonary primary lesions may appear anywhere in the lung, post-primary lesions for some reason not understood generally appear first at one or other apex. Each lesion often appears radiologically as an area of localised opacity in the subclavicular area. This lesion was described first of all by Asmann, although the lesion he described was from 1 to 2 in. in diameter and probably consists of a tuberculous lobular collapse. When the lesions are small they are described as minimal lesions. Both these lesions may and often do develop into progressive tuberculous infiltration.

SECONDARY CHANGES.—1. *Casation.*—The tubercle is avascular, and owing to this, and possibly also to the action of tubercle toxins, coagulation necrosis and fatty degeneration frequently ensue. This combined process is known as casation and

results in the formation of a structureless, cheesy mass. Further changes may now occur, either softening, with the development of a "cold abscess" filled with tuberculous "pus", or calcification, with the subsequent formation of gritty masses known as "pneumoliths".

2. *Cavitation*.—Cavities result from the liquefaction of caseous areas, and the expectoration of the resulting debris. They may be no larger than a pea, or may occupy the whole of one or more lobes. A recent cavity has an irregular outline, with rough, shaggy walls and a vascular line of demarcation. It is often traversed by trabeculae, formed by bronchi and vessels which may be partly or completely obliterated, while sometimes the trabeculae consist of condensed lung tissue which originally separated adjacent cavities. In chronic cases, the cavity is surrounded by fibrosed lung tissue forming a pseudo-capsule, and its interior becomes lined by a thin, smooth, false membrane. Small aneurysms may be found, arising either from vessels running in the walls or in the trabeculae of the cavity, the former being the more common. In some cases, where hæmoptysis has occurred, rupture of such an aneurysm is the cause.

3. *Fibrosis*.—Reactive changes in the lung stroma lead to the formation of fibrous tissue. This may occur early or after cessation has taken place.

In the majority of deaths from all causes, old tuberculous lesions are found post mortem near the apex of one lung. These consist of small nodules of arrested disease, with thickening and dimpling of the adjacent pleura.

DISSEMINATION IN THE LUNGS.—The disease may spread from the primary peri-bronchial deposit—(a) by direct infiltration; (b) by the peri-bronchial lymphatics and capillaries, leading to a racemose appearance or to peri-bronchial fibrosis; (c) by the subpleural and interstitial lymphatics, with localised miliary dissemination; (d) by inhalation into a bronchus of tuberculous material, which is then carried to other parts of the same or to the opposite lung—this not infrequently happens after hæmoptysis and in cavitation; (e) by the blood vessels, e.g. generalised miliary tuberculosis may result from erosion of a caseous tubercle into a vein.

The pathology of the clinically distinguishable forms of pulmonary tuberculosis will now be described.

1. *ACUTE MILIARY TUBERCULOSIS*.—A primary caseous focus may be discovered at the apex of one lung, in the bronchial glands, or at some distant spot in the body. Local erosion of a vein may be found, accounting for the dissemination of the disease. The lungs are usually studded with minute grey tubercles, the smaller ones requiring a hand lens for their recognition. In very acute cases death occurs before any secondary broncho-pneumonic changes take place. Miliary tuberculosis may develop as a terminal event in chronic fibro-caseous or fibroid tuberculosis. The tubercles are then found in large numbers around the old foci of disease, but to a less extent in the more remote portions of the lung.

2. *CHRONIC MILIARY TUBERCULOSIS*.—Reports of cases of this condition were commoner before the recognition of sarcoidosis and many cases were probably erroneously diagnosed. It is questionable whether real chronic miliary tuberculosis exists, although even before the use of streptomycin there were great divergences in the rapidity of development of miliary cases and some might almost have been termed subacute although their fatal termination was the same.

3. *ACUTE CASEOUS TUBERCULOSIS*.—Large areas of consolidation form rapidly, which differ histologically from the common chronic tuberculous broncho-pneumonia in that the alveolar exudate is more definitely inflammatory and contains fibrin. In the rare lobar cases, the rapid caseation and the presence of tubercle bacilli show that the caseous pneumonia is a specific process. Firm yellowish patches, which may be confluent, are seen, usually scattered throughout both lungs. The affected areas are airless and sink in water. Softening is generally present in varying forms up to actual cavity formation, which may be extensive, involving even a whole lobe.

isolated conform to the bovine variety. In tuberculosis of bones and joints up to the same age, 29 per cent. of the cases are of bovine origin.

The bacilli may gain access to the body by inhalation, by alimentary ingestion, through the tonsils, through the skin, or possibly, in rare instances, by hereditary transmission.
